MACHINERY.

MACHINERY for manufacturing Ships' Blocks, in the royal dock-yard at Portsmouth. These machines are the invention of Mark Isambert Brunel, esq.: they are the most ingenious and complete system of machinery for forming articles in wood, of any this kingdom can produce, being not less creditable to the country as an exhibition of mechanical talent, than advantageous to the government in the economical supply of an article of such immense demand for the navy. The great celebrity these machines have obtained, and the valuable information their publication will convey to mechanics, has induced us to devote seven of our plates to their explanation, and will apologize for our entering into so long an account of the manufacture of an article so trifling as a ship's block; though even this should not be despised, when its importance in naval affairs is considered, and how often the safety of a vessel may be endangered by the failure of a single block, regulating any important action in a ship's working. It is of great consequence that these, in common with every other part of a ship's rigging, should be made in a most accurate and substantial manner.

The block machines are particularly worthy of notice, as performing most of the practical operations of carpentry with the utmost accuracy and dispatch, and will be found applicable to many other purposes besides the fabrication of ships' blocks. Indeed, in the dock-yard all the small wooden articles required in the navy can, in some part or other, be executed by the machinery in the *wood mill*, as the building containing them is very properly called, and the largest timber is converted and sawn up into any scantling, by several curious circular and reciprocating saws adapted to various purposes. The succeeding operations, performed by the smaller machines, are boring, mortising, many very ingenious applications of turning for a variety of purposes, both in

wood and iron, rivetting, drilling, broaching, burnishing iron pins, &c. as we shall describe at length. The different kinds of blocks used in the rigging of a ship are described in our article **BLOCK**, and also the manner of constructing them by the old method which was then in practice, the machines in question having been erected since the printing of that article, or, at least, brought into use, or we should have described them in their proper place; but even here they are by no means misplaced, being the best examples of practical machinery, of any we could select from the numerous manufactures our country contains, being adapted to perform operations which are generally understood, but which have hitherto been executed by manual labour and dexterity only.

The blocks for the royal navy were for many years previous to 1807, when the machines were set to work, supplied, on contract, by Mr. Taylor, of Southampton, who employed a large mill, containing powerful sawing machines, for converting the timber into the proper scantling for the blocks, but left them to be formed by manual labour, as related in our article **BLOCK**: the mill also gave motion to lathes of the common construction for making the sheaves. Except what was done at this manufactory, and some few curious machines devised by general Bentham, the credit of bringing the block manufacture to its present perfection is due to Mr. Brunel, who has displayed as much judgment in the division of the operations by the several machines, as ingenuity in the contrivance of their parts, which are admirably well calculated to produce their intended effects. The greatest attention has been every where paid to that form of construction which would admit of the most perfect workmanship in the execution; in this, the ideas of the ingenious inventor have been ably seconded

MACHINERY.

by Mr. Henry Maudslay, of Westminster-road, London, who made these machines with the most scrupulous attention to accuracy and durability, at the same time preserving an elegant proportion in their form, which is very agreeable to the eye. The framing of all these machines is made of cast iron, and many of those parts which are exposed to violent and rapid motion are made of hardened steel to avoid wearing: and where this is impracticable, such parts are formed so that they can be readily renewed when worn out. A better proof of their durability cannot be desired, than the circumstance, that the machines have been now finished four years, and have been in continual work during that period, some of them being subject to very violent and rapid action; yet, among forty-three of them, nothing has happened to require any repairs of sufficient consequence to engage the assistance of the maker or inventor; the trifling repairs of the cutting tools, &c. being made by the workmen on the spot, and of all such parts they have duplicates provided, by which any failure can be restored in a few minutes. These circumstances we particularly recommend to the attention of manufacturers who have occasion to employ extensive sets of machinery; for this, when well constructed, though expensive in the erection, is cheaper in the end than imperfect works, which require constant repair, the expence of which is the least evil; as it generally happens that a machine will fail at that time when it is most wanted, in consequence of being then most worked; and the loss occasioned by the stoppage of great works, particularly where many people are employed, is too evident to require our notice. In the same manner, an attention to neatness, in the appearance of machinery, has its advantages, by inducing the workmen to be careful of the machines they work at, to preserve them from the slightest injury, and to keep them clean from dust, which, trifling as it may appear, is a very essential point in the preservation of those parts which are in rapid motion with friction against other parts, for dust getting between such surfaces grinds them away very fast, and in their most essential points.

Workmen and people employed about machines have no interest in their preservation, farther than to avoid such signs of violence and carelessness as may be immediately detected by their superiors; but by introducing an emulation among them, of having the neatest machines in the factory, and of keeping them in the best order, they may be induced to take as much care of them as if they were their own property. This fact is well known to some of the largest proprietors of cotton and woollen mills, though as much neglected by others. The machines contained in the *wood mill* at Portsmouth may be separated into four classes. 1. The sawing machine for converting the large timber into proper dimensions for the small machines to operate upon, consisting of the large machines for sawing up the elm trees from which the shells of the blocks are to be made, and the smaller sawing machines for cutting up the *lignum vitæ* for the sheaves. 2. Those machines which are employed in forming the sheaves. 3. Those which form the iron pins for the blocks. And, 4. Those by which the shells of the blocks are manufactured. They are all situated in one large mill, which consists of two very tall buildings, or wings, having a smaller and lower one between them, lighted by sky-lights in its roof. The lower part of one of the wings is appropriated to the two steam engines, which actuate the whole, as also some immense chain pumps, which are occasionally employed in draining the dry docks. The mill has two engines of thirty horse power, one erected by

Messrs. Boulton and Watt, and the other by Messrs. Murray and Wood of Leeds. Either of these can be applied indifferently to work the chain pumps, or for turning the wood mill, and their power is transmitted by a train of wheel-work to an horizontal shaft, extending along the centre of the middle building, very near its roof, and upon this are a number of wheels and drums, which, by endless ropes and straps, communicate motion to the various machines for making the block shells, which are situated on the ground, in the central building. They are seventeen in number: fourteen of this number constitute three complete sets for making blocks of different sizes following each other, from four inches in length to eighteen; the length in inches being the denomination of the size of ships' blocks. There is also a large machine for boring parts of those very large blocks which are called made blocks, and cannot wholly be made by the machines; it also cuts shot racks by tools for the purpose: and here are two machines for turning *dead eyes*, which are blocks without sheaves, for attaching the ship's shrouds to her sides.

The ground-floor of the wing opposite to that containing the steam engines, is appropriated to seven large sawing machines for cutting up the trees; and the floor over it contains three sawing machines for cutting up the trees of *lignum vitæ*: also, the small machines for making the sheaves, which are thirteen in number, and a small room, containing five machines, where the iron pins are turned and polished. In the upper parts of both wings of the mill are warehouses for containing the immense stock of finished blocks, which are always kept in store for armaments, and several workshops with common lathes, worked by the mill, for making and finishing various small articles of a ship's furniture. Many of them are, in part, made by some of the block machines, in addition to all those kinds of blocks which we have explained under *Block*. Some of these articles are *dozwels*, for uniting ships' timber; *treennails*, *marling spikes*, *serving mallets*, *pump buckets*, and many other trifles which it is unnecessary to particularize. At the top of one building is a large water cistern, kept always full by a pump belonging to the engine, and provided with pipes which conduct the water to every part of the works, and are in every room furnished with screw caps, at any of which an engine hose can be screwed on in the event of a fire, which is somewhat to be dreaded when they work by lamps in the winter time, as the great quantity of chips and saw dust, always lying about in every part of the mill, might be set on fire. To avoid this danger as much as possible, the lamps are included in glasses of a similar figure to a long cask, with a cap on the top, which has holes to allow the smoke to pass out, but so contrived, that it is impossible a spark should escape. Upon the roof-leads at the top of all, are racks for setting up the very large blocks to season by gradual exposure to the weather, or they would, if all at once subjected to the sun or rain, crack and split in all directions, so as to fall to pieces.

We shall commence our description of this ingenious mill by an enumeration of the several processes the blocks and their sheaves are subjected to, beginning with the rough elm and *lignum vitæ* trees, and tracing them through their various stages to the finished blocks with their sheaves, and, in like manner, the pins for them.

The elm trees are first cut into short lengths, proper to form the various sizes of blocks, by two large sawing machines, one a *reciprocating*, and the other a *circular saw*. These lengths of the trees are next cut into squares, and ripped or split up into proper sizes by four *sawing benches*, with

MACHINERY.

with circular saws, and one very large *reciprocating saw*, which is used for cutting up the pieces for very large blocks. These are the seven machines in the wing.

The scantlings, thus prepared for the blocks, are perforated in the three *boring machines*, with a hole through each, to contain the centre pin for the sheaves of the block, and as many other holes in a perpendicular direction to the former, as the number of sheaves it is to have, these holes being intended as the commencement of the several mortises to contain the sheaves.

The blocks are now mortised in the three *mortising engines*, which elongate the holes above-mentioned to their proper dimensions.

The angles of the blocks are now cut off by three *circular saws*, preparatory to reducing them to the elliptical figure they are to have.

The outside surfaces of the blocks are next formed to their true figure by the three *shaping engines*, each of which forms every part of ten blocks together.

The scores, or grooves, are next formed round the block, to receive the rope or strap by which they are suspended: this is done by the two *scoring engines*.

The blocks are now trimmed by hand labour, to smooth and polish them.

For making the sheaves, the first process is cutting pieces or flakes off the end of the trees of *lignum vitæ*, of a proper thickness to form the sheaves: this is performed by three *converting machines*, one a reciprocating saw, and the other two circular saws.

These flakes are made circular, and the centres pierced in two *rounding and centering machines*, or trepan saws.

A hole is now excavated in the centre of each sheave, to inlay the coak or piece of bell metal which is fitted into the centre of each sheave, to form a socket for the centre pin.

The coaks, being put into their places, are rivetted fast by the two rivetting hammers.

In some kinds of sheaves, three small holes are drilled through each sheave, and also passing through the coak, by the *drilling machine*; and short wire pins, cut by the *cutting shears*, are put through these holes; then they are rivetted down at the same time with the rest of the coaks by the rivetting hammer. This method is not always adopted, the coaks being found to be firm enough without these pins or rivets.

The centre holes through the coaks are next broached out to a true cylinder in the three *broaching engines*.

The last process is turning the faces and edges of the sheaves to a flat surface, in the three *facing lathes*, which also form the groove round the edges of them, for the rope which encompasses them when in the block. This completes the machines for making the sheaves. The iron pins are forged by two smiths, in the usual manner of such articles, between two swages or tools, each having a semicylindrical cavity formed in it, so that the two, when put together, form a cylinder. The heated iron being laid in one of these, the other is put over it, and beat with a hammer, by which means it forms the pin to a cylinder. The end of the pin is left square for a very short length. They are in this state turned smooth and true in the *pin turning lathe*, and afterwards polished and made perfect on the surface in the *polishing machine*.

Such blocks as are from four to seven inches in length, are generally fitted with wooden pins, which are turned in a simple lathe called a *whisket*.

There are also two machines for making *dead eyes*, and a large apparatus or boring machine for making the largest sizes of blocks, of that denomination called *made blocks*, some of

which are as much as four feet in length, and with four sheaves. They are of course made up of planks, and this machine is used for boring the holes of the numerous bolts which are used to unite these parts: it is also used occasionally to cut out shot racks. The whole of this list contains 43 machines.

We shall now proceed to a description of the several machines, beginning with the large sawing machines for elm trees, contained in the ground-floor of one of the wings of the mill. In the centre of this room is a vertical shaft turned by the machinery, having a capstan on the lower end of it, round which a rope is passed, to draw any log of timber into the mill from the yard, where the store of elm is kept. The trees are by this means conducted to the first machine, which cuts them off across into proper lengths, to form such blocks as the tree seems best adapted for. Two machines are employed for this purpose, one a circular and the other a reciprocating saw: the latter we shall describe first.

The great cross-cutting Saw.—The tree subjected to the action of this machine is placed on a long frame or bench raised a little from the floor, and at the end of it is erected a frame, composed of vertical posts and cross timber, in the manner of a small and low door-way: through this frame the end of the tree is drawn by the capstan above-mentioned, its end projecting as much from the surface of the frame as is intended to be cut off; and it is fastened in the frame from rolling sideways, by a lever, which can be readily made to press upon it and hold it down. The saw itself is a straight blade, fixed into a wooden handle or pole at each end, to lengthen it: one of these handles is connected by a joint to the upper end of a lever, bent like an L, and having its centre beneath the floor: the horizontal arm of the lever is connected by a spear rod, with a crank on the end of a spindle near the ceiling of the room, the motion of which is regulated by a fly-wheel. By this means the saw has a reciprocating motion from right to left, nearly in a horizontal position, and exactly across the log it is to cut off, imitating in its motion the carpenter's hand saw, considering his arm as the arm of the bent or L lever. The teeth of the saw are of course on the lower side of the blade, and are sloped so as to cut in drawing towards the lever. It rises and falls freely upon its joint at the end of the lever, and can be lifted up by the handle, at the opposite end of the blade, to take it off its work, which it follows up, by its own weight. The machine being at rest, is prepared for work, by fixing the log in the frame as before mentioned, so that the surface of the frame intersects the log at the place where it is intended to be cross-cut. The saw, which was before lifted up by its handle, to be clear above the log, is now suffered to rest upon it, in the place where the cut is to be made; and to guide it at first setting in, the back of the saw is received in a saw kerf, made in the end of a piece of board, which is attached to the frame over the saw, but slides up and down in a groove to reach the saw at any height, according to the thickness of the log lying beneath it. Being thus prepared, the machine is put in action by a rope or strap which turns the fly-wheel and its crank. This giving a vibration to the bent or L lever, causes the saw to reciprocate horizontally across the tree, until it cuts it through: it follows up its cut by its own weight alone, but the attendant can at any time lift up the saw from its work, though its motion continues, by means of a rope which suspends the handle of the saw when required. As the saw gets into the tree it quits the guide above-mentioned, which becomes the less necessary as the saw goes deeper; a saw having no tendency to alter its first course, when cutting across the

grain of the wood. We admire the simplicity of this machine, which nevertheless executes its work with much accuracy and expedition. It might be very usefully employed in many situations where great manual labour is spent in cross-cutting large logs of timber.

The cross-cutting circular Saw.—This machine is for similar purposes, and stands close by the former. It is a circular saw, whose spindle is so mounted, as to move in any direction parallel to itself; the saw all the while continuing in the same plane, and revolving rapidly upon its axis, cuts the wood it is presented to, and as it admits of being applied at first on one side, and then on another side of the tree, a saw of moderate dimensions will be sufficient to divide larger trees, than could otherwise be done by it.

Plate I. (Block-Machinery) contains two plans and two elevations of this machine. *Fig. 1* is an elevation, shewing the tree *A A* (which is to be cut) lengthways. *Fig. 2* is taken in the other direction, and therefore shews the tree endways. *Fig. 3* is a plan, answering in its position to *fig. 1*, and shews the whole of the mechanism; but the plan (*fig. 4*) only contains the lower parts. The same letters of reference refer to all the figures. *A A*, as before mentioned, is the tree intended to be sawn across: it lies upon a framing of timber *B*, which may be considered as its bench or support. Across the end of this frame a strong timber, or ground sill, *C*, is framed, and in this two uprights, *R, S*, are erected, which, with a cross beam at top, form the frame, which gives the means of confining the tree upon the bench *B* while it is cut. This is done by means of a lever *D*, one end of which is hitched under a bolt put in a hole in the post *S* of the frame, to serve as a fulcrum, and the other end passes between the face of the post *R*, and a piece of wood, *a*, fixed thereto, and the lever, being forced down upon the tree, is kept down by a bolt put through a hole in the piece *a*, and also into the post. The other end of the lever is retained by a piece of wood similar to *a*, (see *fig. 1*.) fixed to the post *S*; by this means the tree is held steadily whilst it is sawn. *T* is a roller, or capstan, to advance the tree forwards on the bench: it is turned round by means of the handspike *E*, which is fitted loosely upon the centre pin of it, and has a small click engaging the teeth of a ratchet wheel *b*, fixed fast upon the gudgeon or centre pin. The handspike, being worked in the manner of a pump, turns the roller about a few teeth of the wheel at every stroke, and by a rope wound on the roller draws up the tree: *d* is a click which detains the teeth of the ratchet wheel, and prevents the roller running back, after being moved by the handspike. A framing of wood is placed beneath the tree at *F*, to form a continuation of the bench *B*, but leaving a space between it and the front of the beam *C*, for the saw to descend into when it divides the tree, when the frame, *F*, will support the piece cut off. A piece of wood is fastened down upon the frame *F*, at *f*: by means of a screw, it acts as a stop to the end of the tree, and measures out the quantity to be cut off from the end of it: it is of course adjustable, and may be fixed at any distance from the end of the bench *B*, according to the length intended to be cut off the end of the tree. We now come to describe the mechanism connected with the saw, which is shewn by *G*, fixed on the end of a spindle *g*, mounted in a frame consisting of two side-beams, *H, H*, connected by cross pieces, *I, I, K, L*, and strengthened by diagonal bolts or ties, *e, e*: the top cross piece is formed of iron, as shewn in *fig. 3*, and its ends are jointed to the end of a frame *M M*, poised in the manner of the balance-beam of a draw-bridge, on a fulcrum supported by the fixed framing of the machine, consisting of two posts, *N*, extending from the floor to the ceiling, and connected by a cross beam *O O*. By this means, the spindle of the saw can be moved in any

direction at pleasure, but always preserves its parallelism, ascending and descending by the inclination of the frame, *M M*, upon its fulcrum, and moving from right to left by the frame *H*, swinging upon the joints connecting and suspending it: from the former the saw receives its motion from the mill by a strap *b*, which encompasses a pulley *i*, *figs. 1* and *2*, contained in an opening of the iron top, *L*, of the frame *H*; it is fastened on a short spindle, which is exactly in a line with the joints connecting the two frames, *M M* and *H*: upon the same spindle is another pulley *k*, which by the strap, *P P*, gives motion to a pulley *l*, fixed on the spindle of the saw; *m, m, figs. 1* and *2*, are two small wheels to guide the strap, and tighten it up, if necessary, when it stretches; the main strap, *b b*, is guided over pulleys *n*, which, being near the centre of motion of the frame *M*, are not materially affected by the motion of the frame either to tighten or loosen the strap which passes round a large drum, turned by the mill. The attendant has government of the machine, to move the saw in different directions by two winch handles, *V* and *W*: the latter of these is on the end of an axis *w*, having two pinions upon it, which operate upon two racks at the end of wooden rods, *Q, Q, figs. 1* and *2*, which are connected with the end of the great frame, *M M*, at the same joints which connect the two frames together; so that by turning this winch, *W*, in one direction, it elevates the saw, and in a contrary direction, depresses it, by inclining the frame, *M*, on its centre. In like manner, the handle, *V*, gives motion by a wheel and spindle to a similar spindle *v*, which actuates by its pinions two rods, *X, X*, jointed to the suspended frame *H*, and therefore moves the saw nearer or farther from the workman who stands at the frame *N N*; the two frames, *H* and *M*, are greatly strengthened by the rods, *Q, Q*, and *X, X*, being connected with them; for as the two pinions act equally upon the two rods, and thus move both sides of the frame alike, they preserve them from twisting, which would cause the spindle of the saw to deviate from the parallelism; but to have this effect, it is necessary that the pinions should fit their racks accurately. For this purpose, the rods, *Q* and *X*, to which the racks are affixed, are supported behind by two rollers, *y, y*, applied to the back of each. These rollers are fixed in a triangular iron frame, the third angle of which is fitted upon the axis of the pinions; and by this means, the teeth of the racks and pinions are always kept in accurate contact, though the racks necessarily alter their inclination at times, according to the position of the frames to which they are joined.

The operation of this very ingenious machine is almost evident from the description. The tree being fixed, the attendant takes the handles *V* and *W*, one in each hand; and by turning one or the other, directs the saw at pleasure to any side of the tree. At first he applies it, as in *fig. 2*, and it cuts half through the tree from that side, with very great rapidity; then he gradually raises it up by the handle *W*, and cuts into the log at the top side; but all the time the saw continues in the same plane: and at last he brings it over to the opposite side, and cutting through it there, the log is separated, even if it is nearly of the same diameter as the saw. The saw is now moved by its handles to be clear of the tree, the piece removed, and the tree advanced to cut another length. This machine is so expeditious and accurate in its performance as to take the lead of the other, except for such trees as are of a size too great for the circular saw. It has, since its first erection, received an addition of a rack and pinion to the frame *R S*, for holding the tree, which presses down the tree instead of the lever, and holds the wood in the manner of a vice or press: by this means, the saw can now

MACHINERY.

be used for sawing the pieces into squares, after they are cut off the tree; and for cutting them up to form different sized blocks, or for sawing up any other timber. The next machine we shall describe is

The great reciprocating Saw, for cutting up trees lengthwise.—In this machine the saw works vertically: it has an horizontal carriage, on which the timber is fastened; this passes through a vertical frame with grooves, in which another frame slides up and down in the manner of a window-fast, and has the saw stretched in it. The saw-frame is moved up and down by means of a crank on an axis beneath the floor, which is turned by means of an endless rope. At every time the saw rises and falls, it turns a ratchet-wheel round, by means of a click, a few teeth; and this has on its axis a pinion, working a rack attached to the carriage of the tree, which by this means is advanced: at every stroke, the saw makes a proper quantity for another cut. The saw-frame is adapted to hold several saws parallel to each other, for sawing a tree into several boards at once, when required. Besides these machines, the wing contains four of

The circular sawing Benches.—These machines are used for cutting the wood still smaller, after the other machines. These machines are a bench, similar to a carpenter's, having a spindle extending across it just beneath the boards, with a circular saw fixed upon it, which comes up through a crevice in the bench; and as it revolves, the workman applies a piece of wood to it, which it cuts with amazing rapidity. The wood is guided by a long wooden ruler, fixed on the bench, parallel to the plane of the saw. The wood is applied to this guide-ruler when cutting, and this regulates all the wood it cuts to the same breadth; but the guide-ruler can be quickly adjusted to any distance from the saw, being attached to the bench by radius bars similar to a parallel ruler, so that it will always be parallel to the saw. We have been thus concise in describing these circular saws, and the great reciprocating saw, as they are the only machines in the mill which do not shew a completely original design, or which have any resemblance to other machinery. The reciprocating saw is such as is common on the continent and in America, and the circular saws have been long in use in this country. See *Saw-Mill*.

One of the sawing benches is much longer than the others, being continued the whole length of the house. It is used for sawing the edges of long planks to a straight line, after they have been cut up from the trees by the great reciprocating saw. It has a carriage for holding the plank, which is advanced towards the saw by a rack and pinion, which the workman turns by a winch in front of the bench: the plank is held in the carriage by its ends, one end being applied against a stop, similar to that which a carpenter's bench has for stopping a piece of wood, while it is planed; the other end of the plank is forced up to this stop by a screw, attached to the carriage, but in such a manner that it can readily be fixed at any part of its length, to hold planks of different lengths. The plank, when of great length, is kept down to bed firmly upon the carriage, while it is sawn by a roller, which presses upon it very near that part of the plank which is passing the saw. This roller is pressed down on the plank by the weight of a long beam of wood set up on end, the roller being fitted in the end of it. This beam is fitted, in guides which permit it to rise and fall, to accommodate any inequalities in the thickness of the wood or plank which passes beneath it. This concludes our description of the machines in the wing on the ground-floor. The machines contained in the floor over the great sawing machines are devoted to converting or sawing up the tree of

lignum vitæ, for the sheaves, and the small machines for forming the sheaves. The first is

The reciprocating Saw for converting the Lignum Vitæ.—This machine is somewhat similar to that first described for the elm trees, but made on a smaller scale and with more accuracy. The saw is stretched in a wooden frame, which is necessary, because, being for the hard wood, it is cut with a much finer tooth, and the blade is much thinner, so that it wastes less wood in saw-dust than the former. The tree of *lignum vitæ* is placed horizontally, being held in a machine, which is, in fact, an enormous vice, though very different in appearance: it is opened and shut by two screws instead of one, as the common smith's vice, and these screws are both moved at the same time by means of cog-wheels connecting them, so as to move the jaws of the vice parallel. This machine is used for cutting the ends of the tree into flakes of the proper thickness, to form those sheaves which the diameter of the tree is best adapted to make with the least waste. The vice which holds the tree is provided with a screw, which advances the whole together towards the saw a proper quantity at every time a sheave is cut off, to cut another of the intended thickness. For this purpose, the vice is stationed upon a carriage fitted upon proper sliders, so that it advances truly parallel, in order that the pieces it cuts off may have parallel sides. This machine is only used for converting the largest trees of *lignum vitæ*, which are drawn up to the floor on which these machines are situated by a crane worked by the mill, so as to occasion little more trouble than if they were upon the ground: the smaller trees are cut up in a very curious machine.

The circular Saw for converting the Lignum Vitæ.—This operates with a revolving saw, which is applied to the outside of the tree, which at the same time turns round to present every part of its circumference to the action of the saw. By this means the saw will cut a tree of nearly as great a diameter as itself, and make a very flat section. We have been compelled, from the number of our plates, to omit a drawing of this machine, and must, therefore, attempt a verbal description.

The spindle of the circular saw is fitted in an iron frame, which moves in a fixed vertical axis, in the manner of a gate or door. The saw spindle being vertical, the saw itself is of course horizontal, and its centre describes the arc of a circle when swung upon its axis of motion, but continues in the same plane. It is turned, like the other machines, by an endless band, which is conducted over pulleys, on an axis concentric with the axis of motion for the saw-frame; by which means the band continues with the same degree of tension in all positions of the frame supporting it. The vertical axis of this saw-frame is supported between the points of centre screws belonging to an iron standard, which is attached to two vertical iron columns, extending from the floor to the ceiling of the room, and which constitutes the chief framing of the machine. The tree of *lignum vitæ*, being previously cut into lengths of two or two and a half feet, is fixed in a chuck or clam at the top of a vertical spindle, which is fitted in a socket, in the middle of a cross-bar, sliding between the two vertical columns. This cross-bar has two iron rods extending up from it to another similar one, also sliding between the columns, these forming an iron frame which rises and falls at pleasure, in the manner of a fash frame, by means of a large screw, which is received into a nut, formed in the middle of the upper cross-bar of the frame. The lower end of the screw rests in a step in the middle of a fixed cross-bar extending across from one column to the other, and perforated with two holes for the iron

MACHINERY.

iron rods forming the sides of the frame to pass through as they rise and fall. The screw has an iron cross forming four handles to turn it by, and a ratchet wheel and click to prevent its running back. The chuck or clam at the upper end of the vertical spindle is of that kind called universal, and has two jaws, between which it will hold trees of different dimensions; but both clams approach or recede from the centre by the same movement, so as to keep the tree always nearly in the centre of the vertical axis. It is accomplished by fitting both clams in a groove formed across the face of the chuck, and both are moved by one screw, one part of which is cut with a left, and the other with a right-handed thread, so that in turning the screw by a wrench, the jaws open or shut, and the wood can be fixed in with as much ease as in a vice, but always very nearly in the centre of the chuck. A rotatory motion is communicated to the vertical spindle by a cog-wheel fitted in a socket made in an iron plate, which is the basement of the two columns. The centre of this wheel is exactly in the line of the vertical spindle, which is formed to a square, and is received through a square hole in the centre of the cog-wheel, but has liberty to slide freely up and down through the wheel. This is turned round by means of a pinion fixed on the lower end of an upright axis, which rises up a considerable height by the side of one of the vertical columns, and has a small winch upon the top of it, by which the workman turns it round, and thus causes the great cog-wheel with the vertical spindle and wood to revolve at whatever elevation it may be, according to the height the sliding frame is raised by its screw.

The operation of the machine is this; the wood, being fixed at the top of the vertical spindle, is raised by turning the great screw to such a height, that the saw is opposite that place in the tree where it is intended to be divided. The saw is in constant motion by the mill, and the attendant presses it by a lever (fixed to the saw-frame) against the wood, which it cuts into very rapidly. At the same time he is doing this, he turns the vertical spindle (with the wood) round by means of the winch, which communicates with it by the wheelwork, so that the tree applies all parts of its circumference in succession to the action of the saw, which will by this means cut through a tree nearly twice its own radius, and in consequence of its revolution makes a very flat section, which will be exactly parallel to the last it cuts off, so that the flakes will be of the same thickness in all its parts. When the piece is thus separated, the workman swings the saw out of the way of the wood, and turns the screw by its cross handle, to raise up the frame, with the spindle and tree, the proper quantity to cut off such a thickness as will form the sheave intended. This quantity is measured by the screw, which, as before stated, has a ratchet wheel upon it, with a click to prevent it running back, which the weight of the iron frame, spindle, and wood supported by it, would otherwise force it to do. The workman counts a certain number of these teeth by the noise they make in passing the click as the measure of the proper elevation of the wood: by this means the operation proceeds with great rapidity, and another piece is cut off, until the whole length is cut up, when the workman relieves the click, and the screw runs back, letting down the spindle ready to receive another length of tree which is cut up in its turn. There are two of these machines close to each other, one for the larger and the other for small trees.

The plates of lignum vitæ, thus cut off the end of the trees, are sawn to a circular figure, and a hole pierced through the centre of each preparatory for turning them

The Crown or Trepan Saw.—See Plate II. *figs. 1, 2, and 3.* *Fig. 1* is a horizontal section through the centre of the axis, *Fig. 2* is an elevation of the whole; and *fig. 3* an end view. *A A* is a cylindrical saw with teeth formed upon the end of it, in the manner of a surgeon's trephine, or the crown wheel of a watch. This saw is fixed upon a chuck *B*, (*fig. 1.*) which is fastened, by screwing to the pulley *D*, turned by an endless belt. This pulley and saw are fitted to slip round freely upon a fixed axis or tube *E*, supported by being screwed to a standard *F*, erected upon the iron frame *K R*, on which the whole machine is built. *G* is a standard, having a screw *H* through the top of it, and exactly in a line with the centre of the tube *E*. At the end of it is a cup *b*, which, when advanced by the screw, exactly meets the end of the fixed tube *E*, and between these two surfaces, or rings of surfaces, the piece of wood to be rounded is held, by screwing the screw tight up. The wood is shewn in a section at *I*, *fig. 1*, within the saw. The saw slides backwards and forwards upon the fixed tube *E*, and can be thus presented as it revolves against the piece of wood, to cut through it, and reduce its circumference to a perfect circle of the size of the interior diameter of the saw. The fixed tube *E* has a cylindrical spindle *K* fitted within it, which is turned round by a pulley *L* fixed in the middle of it, and turned round like the other by an endless strap or belt. This spindle has a drill screwed into the end of it, to perforate the centre hole in the sheave; and it can be moved endways to bring it up to its work in the same manner as the other. Indeed, it is caused to advance or retreat at the same time with it, by means of two connecting rods *b, b*, which pass through holes in the standard *F*, and are at their ends united by screws, to collars which are fitted upon sockets, formed in the central part of the pulleys *D* and *L*, so that the collars admit the pulleys to turn round freely, independent of them; but when either pulley, with its spindle, is moved endways, it obliges the other to partake of the same movement. The two collars are shewn separately at *X* and *Y*, and the standard *F* between them. The farther end of the spindle *K* is supported by a collar in a standard *M*, also erected upon the frame *R*. The motion endways is given to the saw and drill by a lever *N*, situated beneath the frame *R*. The vertical arm *n* of this lever is forked at the upper end, as shewn separately at *Z*, and has notches cut in the extremity of each fork, to receive two pins projecting from the sides of a collar *c*, fitted on the end of the spindle *K*, which turns round freely in the collar, but commands the motion of the spindle endways. The lever *N* is raised up, and the spindle kept back by means of a spring *O* fixed to the frame of the machine, so that when left to itself, the saw and drill always retreat back as far as they can. In this state the workman takes a piece of the lignum vitæ, which is of an irregular figure, being the shape of the section of the tree. This he places against the end of the fixed tube *E*, and screws it fast by the screw *H*. He now depresses the handle *N*, and thus advances the saw and drill, as they are turning all the time, against the wood, which the former perforates in the centre, while the latter cuts off those parts which project beyond the circle, leaving the wood round on the edge and ready for the next operation, which is performed by

The Coaking Engine.—This machine prepares the sheave for the reception of a bell-metal bush, or centre piece, called the *coak*, one of which is fitted into each side of the sheave, to surround its centre pin, and avoid wearing. This piece of bell-metal, or coak, is shewn in *fig. 9* of the plate: it has a cylindrical part *a*, which passes through the centre hole of the

MACHINERY.

the sheave, and has a hole through it for the pin of the sheave. This, which is called its *barrel*, has at the end a shoulder, or flaunch, of the form of *d*, that is, a circle having three ears projecting from its circumference, which are inlaid into the wood, and thus keeps the coak from turning round in the sheave. This is shewn at *fig. 4* of the plate: *e* is a ring of the same size and form as the flaunch at the end of the coak: it is inlaid into the other side of the sheave, but has a large hole through its centre to receive the part, *b*, of the other coak, where it comes through the centre of the sheave. This part being rivetted down into the ring *e*, secures the two coaks together; but, in some kind of sheaves, they are further fastened by means of a wire-pin put through the centre of each of the three ears, which is also rivetted down. The first operation which is therefore performed on the sheave, after rounding and centering the wood for it, is cutting a hole, of a proper figure, for the reception of the brass coak. The engine for performing this is described in the lower part of *Plate B*, of which *fig. 4* is a front view of it; *fig. 5*, an elevation taken on one side; *fig. 6*, a plan of the top of the frame; and *fig. 7*, a plan of the lower part where the sheave is fixed. This is, in all the views, marked *A*: over this a small spindle, *B*, is situated; it is mounted in a frame *C C*, and turned round with great velocity by an endless band passing round its pulley *a*, and conducted over the pulleys *D, D*, *fig. 5*, away to a drum, turned by the mill. The end of the spindle has a cutter screwed into it, such as is shewn separately at *X*, formed out of one piece of steel, with three cutting edges, which cut out a circle of the size of each of the three ears projecting from the edge of the coak. The frame, *C C*, of the spindle is fitted to slide up and down on two vertical rods *E*, fixed in the framing; and the depth to which it falls is determined by a small screw *b*, *fig. 5*, on the point of which the frame rests. The sheave, *A*, is fixed to a chuck *F*, which has a very short axis, received into a socket in the middle of the lever *G*, attached to the frame by a centre-pin, *e*, at one end, and the other is used in the manner of a handle, to move the lever on its centre, and by this means remove the sheave away from the spindle, so as to give it any required excentricity from the spindle; in which case, the cutter, *X*, will cut out a circular hole in the sheave, at any required distance of the centre thereof. The chuck, on which the sheave is fixed, has three arms, *1, 2, 3*, *fig. 7*, projecting at equal distances from it: these are detained at pleasure by a detent *f*, which is forced towards it by a spring: the frame of the spindle, when raised to its greatest elevation, is suspended by a spring-catch *H*; and in this state the cutter is raised up out of the way. The workman now prepares the sheave for coaking, by fixing it on the chuck *F*. To explain the manner of doing this, see *fig. 8*, where *N* is a screw passing down through the centre of the axis and chuck, and has a screw cut on the lower end; and by means of a nut *M*, *figs. 4* and *5*, tapped upon it, the pin can be forcibly drawn down through the axis. The upper end of the pin is, as its figure shews, of a conical figure, and fills a hole through the centre of a steel ring *O*, which is situated upon the face of the chuck, immediately over its centre. The external diameter of this ring fits the inside of the hole, through the centre of the sheave, which is by this means fixed to the chuck: but to hold it fast thereupon, the ring is divided by a saw into three segments, and a piece of watch-spring, *P*, being put round them, in a groove formed for its reception, keeps the three together, and always collapses them upon the central pin *N*; but on turning the nut, *M*, the pin is drawn down, and its conical head expands the three segments, so as to jamb them fast into the inside of the sheave,

and by this means fixes it fast. This contrivance of an expanding chuck, which will fasten into holes of different sizes, within certain limits, and always preserves its concentricity, is extremely ingenious, and is a very valuable tool for turning many small articles in the lathe. The workman thus fixes the sheave to its chuck, to perform which, with convenience, he pulls the end of the lever, *G*, so far forwards, that the axis comes as far as it can within the circular frame *K*, which supports the machine; but when the sheave is fixed he returns it, so as to come nearly concentric with the spindle. This point is determined by shooting a small bolt *g*, *fig. 4*, beneath the lever, *G*, forwards, and then its end stops against the fixed point of an adjusting screw *b*. He now, by relieving the spring-catch *H*, suffers the spindle to descend till it rests on the point of the stop-screw *b*. In this state, the end of the cutter is as much beneath the surface of the sheave as the thickness of the shoulder *d*, *fig. 9*, of the coak; but the cutter is within the centre hole, at least in part, though, in descending as it revolves, it cuts away the wood, on one side the hole, as much as will enlarge its diameter on that side to the size of the circle of the shoulder, *d*, of the coak from which the three ears proceed. The workman now draws the handle of the lever, *G*, away from the spindle, until the bolt is stopped against the point of the opposite stop-screw *k*, as it appears in *fig. 7*. In this situation, the sheave is in that position, that the cutter is so far removed from the centre of the sheave, as to cut out the cavity to contain one of the semi-circular ears of the coak. The lever, *G*, is now pressed against the other stop-screw *b*; the catch, *f*, is relieved from the arm, *i*, of the chuck, by which it is turned round; and in this motion the cutter enlarges the centre hole to the third of a circle of the proper diameter to receive the coak: when the succeeding arm, *g*, comes to the detent, he moves the lower, *G*, out from the centre again to the stop-screw *k*, and thus cuts the second ear. The lever is now returned; the chuck turned round; and a third cavity formed in the same manner as the former; the lever being returned again to the screw *b*, the chuck is turned round to where it set out, and thus completes the enlargement of the centre hole, and the cavity is prepared for the reception of the coak. The sheave, being removed from the chuck, is put on again, with the other side uppermost; and to ensure the ears being exactly opposite to each other on the different sides of the sheave, a small button is let into a hole in the face of the chuck, at the same distance from the centre as the semicircular ear, and of the same diameter as that is; being, therefore, of the same diameter as the cutter, this button is forced upwards by a spring; but while the first side of the sheave was cutting, it was pressed down flush with the surface of the chuck, and was not in use: when the second side is to be cut the sheave is turned round on its centre pin (which is the ring *O*), before fixing, until the button springs up into one of the cavities for the ears, and is placed in such a part of the chuck, that it determines the position of the sheave upon it, so as to cause the ears to be opposite to each other. Being thus fixed, the operation of cutting the second side is exactly the same as the first. This coaking engine is a very complete and ingenious machine, and operates in the most perfect manner to inlay the coaks, and will serve many different sizes, as will be understood from its various adjustments. These are; the stop-screw *b*, which regulates the degree of enlargement the centre hole shall have to receive the shoulder of the coak: the screw, *k*, determines the distance of the centre of the ear from the centre of the sheave; the diameter of the ear must have the cutter *x* suited to it, for which purpose it screws to the spindle: and lastly, the screw, *b*, governs

b, governs the depth to which the cavity is excavated, and must be equal to the thickness of the shoulder *d*, *fig. 9*, of the coak. Two coaking machines are used at Portsmouth, both effecting the same purpose as that we have described, but one of them in its structure differs very materially from our drawing. This is the largest machine. The spindle of the cutter is fitted in a frame, which is connected by joints with a second frame, having a swinging motion on a vertical axis in the manner of a double folding door, or more exactly like the frames of the great circular saw first described, if the spindle of it was placed vertical instead of horizontal; and it receives its circular motion by similar means. This spindle has not the power of ascent and descent, but it is evident it can, by the two frames, be moved to any spot near the centre of the sheave that is placed beneath it. The cutter is made to cut out the proper shape, by means of a hole cut in a piece of fixed brass plate, which is of such a figure, that a pin or collar, concentric with the spindle, being traced round its interior surface, will guide the cutter so as to excavate the proper figure in the sheave, which is fixed on a chuck beneath it, but cannot be turned round, which, from the construction of this machine, is unnecessary, as the cutter traverses all the space which is to be cut out, but cannot move any further, being limited by the brass plate. The chuck for the sheave is fixed at the top of a frame which rises and falls with the sheave, to adjust the depth the cutter shall cut, and the chuck is let down clear of the end of the cutter every time the sheave is to be shifted. This rising and falling is performed in a very convenient manner by means of a screw which elevates the frame, and has upon it a barrel, round which two cords are wound in opposite directions. These cords are conducted over pulleys to two treadles situated beneath the frame of the machine, so that by pressing the foot on one treadle, the chuck and sheave are raised up, and by the other, it is let down, and in either case the screw retains it where it is placed. The frame is provided with a stop-screw, which will determine the height to which it shall rise, and consequently the depth to which the cutter excavates in the face of the sheave.

The bell-metal coaks are cast in sand, in the manner described in our article **CASTING**, from accurate patterns made for the purpose, of which they have a great variety of all sorts for the different sizes. The pattern, or core, which is inserted in the sand for forming the hole through its centre, is not a smooth cylinder, but has two projecting threads which encompass it spirally, in the manner of a very coarse screw; so that when cast, the interior surface of the central hole through the coak is not a smooth cylinder, but has two spiral cavities, or chambers, winding round within it, in the manner of the spiral scores within a rifle gun barrel; but these cavities do not reach the ends of the hole, which is therefore circular at the two ends. These chambers are intended to contain a supply of grease to the centre pin, when the block is in use, as will be more fully described.

The coaks, being put into their places, have holes drilled through the centre of each ear, by a very simple

Drilling Machine.—This bears a great resemblance to a common turning lathe, to the spindle of which a small drill is fixed, immediately opposite to it. In the place of the back puppet of the lathe, is a flat plate or tablet, against which the sheave is placed, and by a screw advanced against the drill, which is all the time in rapid motion. The proper place for drilling the hole is determined by marks punched in the pattern from which the coaks are cast, and thus occasion similar marks in the centre of each of the ears of every coak, by means of which the drill point is guided to the right place, and quickly penetrates through both the coaks and

the sheave also. The pins to fit into these holes are made of copper wire, which is chopped or cut into lengths in the most expeditious manner by a strong pair of shears, having a stop or gauge fixed at the proper distance behind its blade, to stop the end of the wire, and point out the proper mark where it is to be cut. These pins are driven into the holes through the sheave, and in this state the sheave is ready for rivetting, to fasten the pins in, and to unite the two parts of the coak firmly to each other. This is done by

The Rivetting Hammer.—It is delineated in *figs. 1*, and *2*, of *Plate III.*; the first an elevation, and the other a plan of the machine. Its frame is a flat iron plate *A A*, which is situated on a strong bench: upon this two standards *B, B*, are cast, and support an axis *a*, turned round by means of a belt on the pulley *b*. The other pulley, *c*, is fitted loosely upon the end of the spindle *a*, and when the strap is upon it, the machine stands still, because the pulley turns round upon its axis. On the middle of this spindle is a wheel *D*, having three cogs, which operate, as it revolves, to lift up the tail of the hammer *E*, which is fixed upon an axis *F*, supported in the same frame, *BB*, as the main axis. A small anvil or stake, *G*, is fixed to the bottom plate of the frame *A*, immediately beneath the face of the hammer, and the sheave, *H*, is presented between them to receive the strokes of the hammer, which is lifted by the cogs of the wheel *D*, and falls upon the sheave three or four hundred times *per minute*. The hammer would not fall so quickly by its own weight, as to reach the sheave before the next cog of the wheel *D*, lifted it up: a spring, *I*, is therefore applied to act beneath the tail of the hammer, and by raising it up to throw down the face of the hammer. This spring is screwed upon a lever *K*, which is fixed on an axis, *L*, extended across the frame, and the other end is sustained by resting on the surface of an excentric circular wheel *M*, fixed upon an axis, which also has a wheel, *N*, fixed by the side of it, and a rope being fastened round this, descends to a treadle beneath the bench, and the workman pressing this with his foot turns the wheel round, and its excentric circle acts upon the lever, *K*, to raise it up, which causes the spring to act with greater force, and the hammer to make a more powerful stroke. In using this machine, the workman takes a sheave, and, lifting up the hammer, applies it beneath the face of it; then by shifting the endless strap, which is all the time in motion, upon the live pulley *b*, the axis, *a*, is turned round, and the hammer beats upon the rivets, so as to fasten them effectually in a very short time. By this the end of the barrel of one coak is firmly rivetted into the other coak on the opposite side, and the barrel being, at the same time, shortened by the rivetting, the sides of the coak are drawn into their cavities with such force as never to be in danger of getting loose. Some kinds of sheaves are found to do as well by merely rivetting down the end of the barrel without using any pins: these were first applied to prevent the possibility of any coaks getting loose; but having been found, in some years practice, to be a needless precaution, it is accordingly discontinued, except in some particular instances.

Broaching Engine.—The sheaves, after being coaked and rivetted, are broached, to make the interior surface of the centre hole perfectly smooth and cylindrical. For this purpose, the sheave is fixed on a flat chuck, at the upper end of a vertical spindle, which turns round, and the broach or borer is forced down perpendicularly through the centre hole of the coak, while the sheave is turning round, boring out the hole as it descends to a true cylinder. The manner of fixing the sheave to the chuck in an expeditious manner, and getting it concentric with the axis, is very well contrived. The vertical spindle is hollow for a considerable depth

MACHINERY.

depth down it, and the borer is a cylindrical rod which exactly fits into this hole in the end of the spindle, and also fits pretty truly into the centre hole of the coak, in the state it comes from the rivetting hammer. This cylindrical rod has a small tooth of steel fixed into it, and projecting a small distance from the circumference of the cylindrical rod, which, as before stated, is of the same size as the hole through the coak of the sheave, and its tooth projects as much as the hole is intended to be enlarged in the operation of broaching.

In fixing on the sheaves, the machine being at rest, the broach is drawn up (by the screw movement which is used to force it down into the sheave), so as to be clear out of the end of the spindle: the sheave is then laid upon the flat chuck, at the top end of the spindle, which is much larger than the sheave itself: the cylindrical borer is next put down through the centre of the sheave, and entered into the hole in the end of the spindle. By this means the sheave is placed on the chuck, exactly in the centre of it, and both being flat, it only requires to be screwed or clamped fast against the chuck, so as to be turned round at the same time with it. This is done by a clamp, consisting of an iron ring of a smaller diameter than the sheave, having two short bars projecting from the opposite sides of it. These bars extend across the face of the chuck, to which one of them is connected by a joint or hinge, and the other by a screw; or, in other words, the clamp may be considered as one bar, having a large hole through the middle of it, one end being hinged to the chuck, and the other drawn towards it by a screw similar to a vice screw; but is so constructed as to be quickly unhooked, and then the clamp bar may be lifted up upon its joint, in the manner of a book lid, to place the sheave under it. The ring or hole through the centre of the clamp, when screwed down upon the chuck, is concentric with the spindle, and thus leaves the centre of the sheave free and clear for the operation of the borer. The sheave is thus, by means of this clamp, fastened down upon the face of the chuck in a moment, and the workman sets the machine in motion. He now, by turning a handle, gives motion to a wheel over head, in the centre of which is a nut, through which the screw in a line with the borer is fitted to work; and this screw as well as the borer being prevented from turning round by appropriate fitting at the end of it, is caused to descend, and force the borer down till its cutting tooth meets the bell-metal coak, and cuts its way through, enlarging the hole to its intended dimensions, and making it truly cylindrical to fit the pin on which it will turn when in the block. It is to be observed, that the interior surface of the hole has two spiral grooves or cavities within it, which are formed in the casting, as before described. These are too deep to be taken out in the broaching, and form receptacles for grease, which is thus always kept supplied to the centre pin, both to diminish friction and avoid wear of the parts. This is a great improvement in the blocks, as, without such receptacles, the pin, if well fitted into its centre hole, as it is and should be, would afford no room for grease, and then the block would require constant attention to keep it supplied, or would always be in want of it. The two spiral cavities do not come to the ends of the hole in the coak, which is therefore a complete circle. By this means, when the pin is in its place, the cavities have no external communication at which the grease can escape.

The Face-turning Lathe.—The sheaves in this state are turned to make the two faces perfectly smooth, and the circumference truly circular, as well as to form the groove or hollow round the edge of it, to receive the rope. The turning is performed in a very complete lathe adapted for

the purpose, see *Plate III. figs. 3, 4, 5, 6, and 7.* *Fig. 3* is an elevation, and *fig. 4* an end view; *fig. 5* is an horizontal plan, and *fig. 6* are various parts shewn separately; *fig. 7* is a cross section answering to *fig. 4*. *A* is the spindle or mandril of the lathe, mounted in the usual style between two standards *B, C*, which are erected upon the main frame or bed *D* of the machine: it is turned round by an endless band on the pulley *E*, and *F* is an idle or dead pulley, on which the band is shifted when the lathe is intended to be at rest, because it turns freely round upon the axis without moving it. On the end of the spindle a chuck, *G*, is screwed, to which the sheave, *H*, is fixed by means of an expanding ring chuck, such as described belonging to the coaking engine, except that the screw, *N*, is tapped into the chuck *G*, instead of having a nut behind it in the manner of the coaking engine, and this screw is turned with a screw driver, which has a square end, and the end of the screw has a square hole to receive it. The tool *a*, which cuts or turns the face of the sheave, is carried in a straight line across it, from the centre to the circumference by a sliding rest, which consists of two sliders placed across each other. One is fixed fast down upon the frame of the lathe at *I*, and has a metal frame, *K*, fitted across it, which slides upon it by means of two parallel pieces *k, k*, which are attached to it on the lower side, and fit upon the dovetailed edges of the lower slider *I*. A screw, the handle of which is shewn at *M*, is fitted within the lower slider, and operates by a nut fixed beneath the frame *K*. To move it along the slider *I*, when the screw is turned by the handle, *M*, upon the end of it; the frame, *K*, has two pieces or rulers *n, n*, screwed down upon it, forming a dovetail groove, in which a slider, *N*, is fitted and moved in a direction across the frame by a screw *L*, which is also provided with its handle *P*. This last slider has a frame *Q*, erected upon it, in the top of which is a groove, to receive the tool *a*, and a piece of metal, *b*, covers it, and can be drawn down upon it by means of a screw, so as to form a clamp which holds the tool down firmly upon the slider. The handle, *P*, of the screw, *L*, is only used occasionally, to traverse the tool across the face of the sheave; it is in general moved by means of a pulley *O*, fitted to slip round freely thereon. This pulley is turned round by means of an endless band *d*, which makes a turn round the pulley *e*, and then passes away and goes round a pulley *R*, which is fixed on the extreme end of a spindle *S*, mounted in a frame *T*, fixed perpendicularly across the great frame *D D*. This spindle has a wheel, *V*, fixed upon it, having fine teeth formed round the edge of it, which are engaged with the threads of an endless screw *W*, cut upon the main spindle *A*. By this means the pulley, *R*, receives a slow motion from the main axis, and by means of the endless band, communicates a still slower movement to the pulley *O*. The band, after having made the turn round this, is conducted round a pulley *e*, which is fixed at the upper end of a flexible spring *X*, attached to the legs of the frame, and thus preserving a proper tension of the band, though the situation of the pulley, *O*, is constantly altering the position of its centre by the movement of the slider *N*, and its frame, *K*, upon the lower slider, *I*, by the screw *M*. The manner of using the machine is this: the sheave is attached to the chuck by a turn of the screw *N*, in the centre of the expanding steel ring, as before described of the coaking engine, and the direction of the spindles movement is such, that the drift of the work always makes the chuck tighter, by working the screw farther in and expanding the ring more powerfully into the hole in the centre of the coak, to make it turn the sheave about with the chuck. Being thus prepared, the strap is shifted to the live pulley *E*, and causes the spindle to revolve and the sheave with it: the

screw, L, is turned by its handle P, to bring the point of the tool opposite the centre of the sheave: the screw of the lower slider is now turned by its handle M, to advance the point of the tool, to touch the face of the sheave as it revolves, and then the screw, P, is put in motion by this means. The pulley, O, is, as before stated, in constant motion, but slips upon the end of the screw. This, at a short distance from the pulley, is formed into a square, and has a clutch or short lever fitted upon it, such as is shown at Y, *fig. 3*. This has a center-piece or socket, having a groove formed round it for the reception of pins attached to a forked lever Y, *fig. 5*, in the manner shown at Z. This admits the clutch to turn round freely within the fork, but is obliged to move an end upon the spindle, to draw it away from the pulley O; and in this state the pulley slips round: but when the lever is moved to thrust the clutch towards the pulley, a pin projecting from it intercepts the arm or lever of the clutch, and turns the screw round with it. In this state the slider, N, traverses slowly along, and the point of the tool, a, advances from the centre of the sheave to the circumference, turning the face of it all the way perfectly smooth and true; to prevent the screw forcing the slider, N, too far, and injuring or breaking it, a rod, z, is provided, which is jointed to the end of the lever y, and is received through an eye, x, attached to the slider N. The rod slides freely through this eye; but by the time the tool has arrived at the circumference of the sheave, the eye, x, has intercepted a nut, p, at the end of the rod, and drawing it, removes the lever y, and by this means disengages the screw from the connection with the pulley O, and thus prevents the danger of breaking the screw: for as soon as the slider arrives at the end of its motion, the screw is disengaged, and its motion ceases.

The groove round the edge of the pulley is turned, at the same time the tool is turning the face of the sheave, by a gouge which the workman holds over the edge or rest, marked E, which is fixed opposite the edge of the sheave, in the manner represented in *fig. 7*, though it is omitted in the other figures. This part of the turning is performed in the usual manner of turning by hand; and the workman has plenty of time to do it, whilst the machine is turning the face of the sheave, which it does without any attention on the part of the workman, except at the first setting out, when he has a little trifle to perform: this is, as soon as the tool has advanced across the face of the metal coak, (and therefore finished the turning of it,) to double the velocity of the machine; for it is found by experience, that the process of turning will be performed to the greatest advantage, when the work revolves with a certain velocity for brass or bell-metal; but in turning wood, it is proper to move nearly twice as quick, being a softer substance, and not liable to heat and soften the edge of the tool, as metal would, if turned with the same velocity. The change of speed in the machine before us, is effected by the wheel which gives motion to the strap, turning the spindle of the lathe: it has another wheel situated close to it, upon the same spindle, but revolving with twice the velocity of the other. They are so near each other, in the same manner as the live and dead pulley upon the spindle A, that the strap can readily be shifted from one to the other while they are at work. Thus, when the machine is first set in motion, and as long as the tool continues turning the bell-metal, the strap is upon the slow pulley; but as soon as the workman sees the tool is beginning to cut the wood, he shifts the strap upon the quick pulley, by which its velocity, and consequently that of the lathe, is immediately doubled, and continues so until the sheave is finished turning; and then the workman returns it back again to the slow pulley, and immediately

after shifts the strap to the idle pulley upon the spindle A, which slips round upon it, and the motion ceases. The slider, I, is not fixed to the frame, D D, in a direction perfectly parallel to the spindle, and therefore the slider, N, is not exactly perpendicular to it, by which means it gives a convex surface to the sheave; and when it is fitted into its block, it will be certain to touch it only in the centre, and thus avoid all unnecessary friction. The chuck G, as shown by its section in *fig. 3*, is turned hollow, and the sheave only applies to a prominent edge at the circumference of it, by which means it will receive the convex surface, when the second side is to be turned, as readily as it did the flat surface, when the first side was turned. The angle of inclination of the slider is very trifling, because the sheave is not required to be very convex; and this convexity will be double the angle the slider, I, makes with the spindle, or, what is the same thing, the difference of the other slider from the perpendicular to the spindle. The screws which fasten the slider, I, down upon the main frame D, are adjustable to increase or diminish the convexity at pleasure.

The turning dust, which this machine makes, is winnowed in a machine, similar to that used in corn-mills, to separate the wood-chips from the metal-turnings, which are returned to the foundery to be re-melted, and used in casting other coaks.

This machine completes the suite for making the sheaves. All the machines we have described display great ingenuity, and much originality of thought, particularly the expanding chuck for holding the sheaves in the coaking and turning machines. Among all the multitude of ingenious tools, used by turners for chucking or fixing their various works in the lathe, nothing was completely adapted to the circumstances of the present case: for as the coak is to be turned to the very centre, and the sheave all across the face, and also upon its circumference at the same time, so that nothing else than holding it by the inside of the centre hole would succeed. It is a valuable tool for many other similar uses. The converting machine, or circular sawing machine, is extremely well adapted to its purpose; and the contrivance of turning the log round, while it is sawing, is most excellent, as it ensures a perfect flat surface, and parallel to the former cut; conditions which would be extremely difficult to fulfil in any other manner. Indeed the great reciprocating saw is not found to be at all equal to it, and is therefore never used, except for such large trees as the circular saws cannot cut through: it would have been unwieldy to have made so large a machine on the construction we have described for the circular saw, many of the trees being eighteen inches and more in diameter. The whole series are calculated for operating upon large or small work; and this is one of the greatest merits of the machines. More than 100 sizes of sheaves are made by them, of all diameters and all thicknesses. It will be proper for us to review all the suite, and point out the means by which they are adapted to the different sizes. In the first converting or sawing machine, the number of teeth of the ratchet wheel on the screw, which the workman passes every time, regulates the thickness of the sheave, and this very accurately; for the screw is cut with a coarse or rapid thread, and the ratchet wheel having several teeth, it gives the means, by counting one tooth more or less, to cut them with the greatest precision to any thickness required.

In the rounding and centering machine, the chuck of the trepan saw is screwed to the spindle, in the same manner as a lathe chuck, and can readily be removed, and another of any size substituted, for the different sizes of sheaves: the drill in the central axis also screws into it, and a great variety

MACHINERY.

riety of all sizes are provided. The whole of this machine is very ingenious and expeditious in its operation.

The coaking machine is universal, and will cut any size, as we have before described. The coaks are cast from a great variety of patterns, suited to the various sizes.

The rivetting hammer, having no parts which are attached to the sheave, will of course apply to any thickness indifferently.

The broaching engine holds any sized sheave, and the clamp which fastens them to the chuck adjusts to different thicknesses: the borer or broach is easily changed for any size; it is, as before stated, a cylindrical rod of the size to fit the centre of the rough coak, and its cutter projects enough from it to clear the hole out.

The facing lathe is provided with a variety of expanding chucks, like the coaking machine, and adapted to all sizes. They are put on by merely removing the conical screw in the centre of the chuck, and putting in another ring around it; the lower slider accommodates for different thicknesses of sheaves, and the common turning rest, *fig. 7*, for the different diameters.

This operation finishes the sheaves, which are now ready to be fitted into their shells or blocks, the manner of forming which we have yet to explain; but we shall first notice the machines for making the iron pins, situated in a small room up stairs. There are of two kinds: first for turning, and others for polishing or burnishing them afterwards. The pins are forged between swages, by two workmen, in the usual manner of such articles, and are cylindrical, except a small part at one end, which is left square, to be inserted into the cheeks of the block, that the pin may not turn round when it is put together, by the friction of the sheave upon its pin.

Pin-turning Lathe.—The lathes for turning the iron pins are the best finished machines of the whole suite, being the last which are made, and by no means the least important in their use, as they turn the largest iron pins, perfectly cylindrical, from end to end in a very short time, and without attendance, except at first; an operation which is very tedious and laborious, when performed, in the usual manner, by hand. We shall be able to give a tolerable idea of this machine without a drawing on purpose, it being compounded of the parts of many machines we have described in our different plates. The reader must suppose a lathe with a triangular bar, in its form similar to that described in our article *LATHE*, but its rest removed from the bar. This is to be fixed over a strong square iron frame, but the puppets of the lathe not vertical; that is, a perpendicular line let fall from the central line of the mandril, will fall clear before the triangular bar, one side of which is upright. This is necessary, because water is used to drop upon the turning tool; and if it fell upon the bar, it would cause it to rust and spoil the fittings. The square iron frame, over which this lathe is fixed, has on one of its sides a long sliding rest, which is in its properties similar to that belonging to the face-turning lathe, except that its long slider is parallel to the direction of the mandril; the tool being supported by a smaller slider perpendicular to this, and moving along upon the long slider by a long screw, which can occasionally be turned by a motion from the mandril, or may be turned by a handle. The tool itself is a cylinder of steel, cut off obliquely, so as to present an elliptic face, the small end of which is the cutting edge; it is held in a holder at the end of the small slider, of similar form to that used for the shaping engine, as will be particularly described hereafter. The lower or long slider, which, as before mentioned, is parallel to, and as long

as the lathe, consists of a rectangular frame (or it may be considered as a large flat bar, with an opening or mortise through its upper side, and extending its whole length, giving it the appearance of a frame), and in this the screw is fitted. On the upper surface of the frame two rulers are screwed at the sides, forming between them a dove-tailed groove reaching the whole length of the frame, and in this groove a small flat plate is fitted, and traverses, by the action of the long screw, from one end of the lathe to the other. The flat sliding plate has a cap-piece or socket screwed down upon it, forming between them a socket for the reception of a short triangular bar or prism, which is the upper slider carrying the tool, and traverses through this socket in a direction perpendicular to the former slider; it therefore advances or recedes directly to and from the pin which is turning in the lathe. The end of the triangular slider has a socket or holder in it, which holds the tool in an inclining position, a little removed from the vertical, in the manner of the shaping engine: the slider has a screw behind it to force it forwards towards the work: the flat plate, which moves in the groove of the lower slider, has an iron arm proceeding from it, which turns upward behind the pin in the lathe, and has a little table on the top of it, to support a small vessel of water, which supplies a small stream to drop upon the turning tool. The screw of the long slider has a small wheel fixed on the end of it, which is turned by an endless screw formed on the end of a small spindle, perpendicular to the direction of the lathe, and is turned by a band, which receives its motion from pulleys on the mandril of the lathe. The pivot of the spindle of this endless screw is fixed in a piece of metal which moves on a centre, to allow the screw to fall down clear of the teeth of the wheel; but when the screw is engaged with the wheel, the piece supporting its pivot is kept up by a catch, which is provided with a rod, in the same manner as the facing lathe: this disengages the catch, and consequently, by letting fall the endless screw, disengages the motion of the long screw, when it has turned the length of the intended pin, so as to avoid the danger of injuring the machine. The pin is, as before stated, forged with a square part at one end: this square end is received into a chuck screwed to the end of the mandril, the form of which is an hollow square prism; but two of its opposite angles are cut clear away, so that it catches the pin by only two of the angles of its square, and by being forced deeper into the prism, it is sure to fit and hold it correctly by these two angles, and with less danger of altering its position, than if there were four angles to the chuck, being certain of a correct bearing. The pin is prepared for turning by a small hole being punched in the cylindrical end of it, a simple tool being used to ensure the punch being set truly in the centre of the end of the pin. The operation of this turning lathe is thus: suppose the motion cast off, and the wheel-work of the long screw disengaged, the tool is moved by turning this screw with its handle to stand at that end of the long slider which is farthest removed from the mandril. The pin is now put in, by inserting its square end into the chuck, and screwing the back centre into the hole punched in the other end of the pin, which being thus mounted, the lathe is put in motion, and the tool advanced, by the screw of the upper slider, towards the pin, until its edge meets it, and cutting it as it turns round to a true circle just at the end. Being thus set in, the wheel at the end of the screw of the long slider is, as before described, engaged with the wheel-work which gives it motion, and this traverses the tool from one end of the slider to the other, cutting a thick shaving off the pin, and turning it cylindrical in its whole length; the small vessel of water

MACHINERY.

before mentioned being attached to the socket for the slider carrying the tool, therefore moves along with it all the way. This cock is set to drop a small stream of cold water on the tool to keep it cool; but the water falls, together with the shavings, clear down through the iron frame, and is caught in a cistern below. The motion of the tool, when it arrives at the intended length of the pin, casts itself off, as before stated, so as to be in no danger of breaking the slider or screw. Three of these machines are in constant use for different sized pins. After being turned, the pins are truly cylindrical and straight, but have spiral lines or scratches traced upon them, in consequence of the edge of the tool not being always perfectly keen. To remove these, and make them perfect, the pins are burnished in

The Polishing Machine.—This consists of three steel dies fixed in a box, and regulated by strong screws to form a triangular opening of any required dimensions. The pin being drawn through these dies, and turned round at the same time, receives a most violent pressure and friction, which burnishes and polishes the whole of its surface in the most perfect manner imaginable. The dies are of course immersed in oil, to avoid the heating of the pin or dies from the friction. This is the general construction of the machine: the pin is fastened, by means of a strong hand vice, to the lower end of a long screw, with which it forms a right line: this screw and pin are placed in a vertical position exactly over the dies, and the screw is enclosed in a nut or female screw, which is made in two halves, and shuts up in the manner of a pair of tongs round the screw, so that they can be opened, and then the screw can be raised or lowered at pleasure, it being properly balanced and suspended by tackle, which gives the means of lifting it with ease. Exactly beneath the screw the dies are fixed, being fitted into an iron frame or box containing the three, each fitted into a proper groove, and adjustable by a screw behind it, to form a triangle of such dimensions as the pin will exactly fill. The interior surfaces of these dies are highly polished, and as hard as steel can be made. The box or frame for the dies is contained in a pan which is filled with oil, and has a vertical tube beneath it, to admit the pin to descend into as it passes through the dies. To prevent this tube and pan overflowing by the immersion of a large pin, a copper pipe proceeds from the vertical tube, and communicates with a large pan, fixed at a little distance behind the dies, and on the same level with the pan which surrounds them. By means of this communication, the united surfaces of the two pans are so large, as not to be materially raised by the immersion of a pin.

In the operation of this machine, suppose the screw at the top of its movement, the pin is fastened to it by the vice at the lower end, biting the square end of the pin. One of the screws of the dies is now screwed back, and this opens or enlarges the triangle between them, that the pin may pass clear through it without forcing. The nut at the top of the screw is now opened, and the pin let down till its square end comes to the dies. The screw of the die is now screwed up hard to bite the pin; and the nut is closed round upon the screw. The machine is now put in motion, and the screw being turned by it turns the pin round, and at the same time draws it up through the dies, which burnish the surface in the most perfect manner; and when they come out, have as high a polish as it is possible for iron to bear, and the surface receives a kind of case-hardening, which enables them to resist wear in a most effectual manner. It is found to facilitate the process of polishing, to rub the pin over with soap before it is put in, as this prevents any danger of the pin having specks in it which are not perfectly polished,

owing to some properties in that part of the iron which cause the dies to abrade or rub up the surface of the iron rather than burnish it down to a polish; but the use of a slight quantity of soap is found to render the process certain.

Machines for making the Shells of the Blocks.—We have now to notice those machines which are devoted to the fabrication of the shells for the blocks: they are, as before stated, contained in the central building of the mill, in the roof of which is the shaft that drums upon it, giving motion to the whole, with very convenient contrivances for detaching any movement at pleasure. This suite of machines, perhaps, displays the greatest ingenuity, or at least the greatest novelty, of any in the whole work; several of the operations, particularly the mortising and shaping, being new principles of working wood by machinery, and are valuable inventions, being applicable to many other useful purposes, when wood is to be formed into small articles, of which a great number are required of the same kind.—The first operation to which the blocks of wood intended to form the different shells are subjected to, is boring in the

Boring Machine.—The pieces of elm to form the different blocks being prepared, and converted to the proper dimension by the sawing machines first described, have two holes perforated through each in different directions; one through the centre of each, which is intended to receive a centre pin from the sheave, and as many others as the block is intended to have sheaves in a direction perpendicular to the former, being intended as the commencement of the several mortises which are to contain the sheaves. *Figs. 1 and 2 of Plate IV.* are elevations of this machine, *fig. 3* an end screw of one spindle, *fig. 4* is a detached view of some part, and *fig. 5* is a plan of the whole machine, the same letters of reference being every where used. A, B, represent two spindles turned by their respective pullies *a, b*, and mounted in a frame similar to the mandril of a lathe; both are provided with borers C, D, formed to edges in the manner of a carpenter's centre bit. The block marked X is held in an iron frame, E L L, by the end of a screw, F, being forced down upon the top of it, and the borers are presented to it by the action of two levers *g G k* and *b H i*, which move on centre pins fixed in the frame of the machine at *g* and *b* (but at different heights from the frame, as is shewn in *fig. 6.*) These levers act upon pins fixed in the frames of the two spindles, which frames are fitted upon dovetailed sliders I and K, so that they advance towards the block when the workman moves the handles, *i, k*, at the ends of the levers in that direction; and the borers, being in rapid motion by their pullies, penetrate the wood very quickly. The proper situation for fixing the block, that the borers may enter at the proper points, is determined in this manner: the frame E L, as the plan shews, consists of three legs rising from the main frame, and uniting together to support the socket in which the screw, F, acts. Two of these legs unite together before they reach the socket. (See L, *fig. 2*; and L L, *figs. 1 and 5.*) In this double leg three small screws, *d, e, f*, are inserted, their heads forming a support, against which one side of the block is firmly held, before the screw, F, is screwed down upon it, and holds it fast upon the head of a screw K, which is the support of the block. But these three screws only determine the position with respect to the borer D; and that it shall pierce it perpendicularly to the side of the block, the borer, C, is caused to penetrate the centre of the block by a gauge, formed out of a piece of iron, shewn separate in *fig. 4.* It has a groove in it, through which the screw, K, passes to fix it down to the

MACHINERY.

the frame, and a blade, R, standing up perpendicular, just beneath the borer D, *fig. 1*, as shewn there at R. One side of the block being pressed in contact with this blade, while the other side is held against the heads of the three screws, determines its situation, so that the borers will form the holes in the exact points required, and which being adjusted by experiments for one block, will bore any number of the same size in the same places. The adjustment for blocks of different thicknesses, is made by the three screws, *d, e, f*, being screwed to project more or less from the frame, that when the side of the block is applied to their heads, the borer, D, will perforate the block in the middle of its width, and perpendicular thereto.—In the same manner, by the gauge, R, being fixed a greater or less distance from the screw K, the borer, C, may be adjusted to bore exactly through the centre of the side it is presented to. The lengths of different sized blocks is accounted for by putting collets of different thicknesses beneath the head of the screw K, which raises the support for the block to the proper height. The slider, I, on which the frame of the spindle, A, moves, is firmly fixed down upon the frame of the machine, but the slider, K, for the other spindle is formed on the top of a frame SS, which has a motion on an axis formed by the points of two screws, T, T, passing through studs projecting from the frame. This frame, and the slider it supports, can be rendered immovable at pleasure, by the points of two stop-screws *m* and *n*, which may be also set to allow it any required latitude of motion. In the former case, when the frame is fixed stationary, as we have considered it in what we have before stated, the machine is adapted for boring single sheaved blocks, the borer, D, perforating the block in the centre. When double blocks are to be bored, the points of the stop-screws *m* and *n* are set at a proper distance asunder, and the frame, being held first to one of them, bores a hole for one sheave, and being then turned over to the opposite stop-screw, formed a second hole at a proper distance from the first. The difference of height between the two borers is rather more than the semidiameter of the sheave, because one is level with the centre, and the other, D, is by the end of the mortise, to adjust this difference for the different diameters of blocks; the frame, SS, has several holes in its sides, at small distances apart, to receive the points of the screws T, T, and the frame, being pitched on any of these different centres, will raise or depress the point of the borer, D, to the proper height for the different sized blocks. The screw, F, has a lever N, fixed upon the top of it, and loaded at the ends with two weights, in the manner of the fly press, and the block being, as before-mentioned, held in its true position, the screw is forced smartly down upon it, and by the momentum of the balls presses very powerfully upon the wood. The screw is provided with a steel ring, fitted upon its point, which has a sharp edge beneath, and this penetrates the end of the block, deeply marking a ring round in it, which is exactly in the centre of the end, and is used to fix the block in a proper position in some of the succeeding machines. The blocks, being thus bored, are subjected to the action of

The Mortising Machine, which cuts out the mortises for the reception of the sheaves. It is delineated in *Plate V.* where *fig. 3* is an elevation in front, and *fig. 5* a vertical section of the lower parts taken parallel to the former; *fig. 1* a horizontal plan, as is also *fig. 4* at a different level; *fig. 3* is an elevation of the whole machine. The machine works as many chissels as the block is to have sheaves; these, as shewn at A, *figs. 2* and *3*, are attached to a frame B *a a k*, which rises and falls with great

velocity, forcing the chissels through the block X, fixed in a carriage CD, which advances after every cut the chissels have made, the thickness of the chip, it is intended to cut out of the end of the mortise at the next stroke. But this advancing movement of the carriage ceases as soon as the mortise is enlarged to its proper length. The reciprocating motion of the frame for the chissel is occasioned by a crank *d*, on the end of the main axis E, which is supported in bearings at each end, one in a cross-bar, F, of the frame, and the other in a standard G, which is erected from the cast iron ground fill, which is the foundation of this whole machine. The axis has a rapid rotatory motion communicated to it by an endless strap, encompassing the pulley H, and the velocity of the motion is regulated by the fly-wheel I. The crank, *d*, has a spear or connecting rod, K, jointed to it, and connected by a joint at the upper end with the sliding frame B, which is formed to a triangle at top, and has a cylindrical rod, *k*, rising from its vertex, and accurately fitted into a socket, supported by framing, erected on the top of the main columns which form the framing. The sides of the lower part of the frame, B *a a*, are formed into dovetail sliders, and received into grooves in the edges of metal bars *b, b*, *fig. 3*, attached by screws to the vertical pillars of the frame. By this means the frame slides freely up and down, without being capable of any deviation from the perpendicular, and the chissel, being firmly fixed to it, moves in the same manner when they descend into the mortise. The frame has two bars, *a, a*, across it, against which the chissels, A, A, are held, by means of a clamp provided to each, which lies behind the bars, and its two ends, *z, z*, come over them in front, with holes to receive the chissels and screws to fasten them. By means of these screws, the chissels are pressed forcibly against the bars, and attached to the frame, but in such a manner that they can be fixed at any distance asunder, or any number may be put on at pleasure, by their respective clamps, to mortise either single, double, or threefold blocks. The carriage CD, in which the blocks are fixed, is an iron frame, sliding on proper bearing in the main frame, and the advancing movement is communicated to it by means of a screw L, fitted through a nut in the centre of the ratchet wheel M, which turns round in a socket, formed in a cross bar, N, of the framing: thus, when the wheel is turned round, it operates upon the screw to advance it, with the carriage and block at the same time: the ratchet wheel is turned round at intervals, by means of a tooth, formed in a rod *e*, *fig. 5*, attached by a joint to the end of a bent lever O, which receives its motion by the other end of the lever, having a roller *g*, which applies itself to the circumference of an eccentric circle or cam, *b*, fixed on the main axis E. By this means, at every revolution of the main axis, the rod, *e*, moves backwards and forwards, and in the period when the chissels are nearly at the height of their ascent, the tooth of the pall or rod, *e*, turns the ratchet wheel one tooth, and by the screw, L, advances the carriage and block the thickness of the chip, the chissels are intended to cut from the end of the mortise, at the succeeding stroke. The ratchet wheel, M, has a cog-wheel, P, fixed to it, which has its teeth engaged by a smaller cog-wheel Q, fixed on a long spindle R, extending to the front of the machine, and has a handle, S, fixed upon it, by means of which the workman can, at any time, turn the wheel round so as to bring the carriage to the proper point for the commencement of the mortise. The motion of the screw is cast off at the proper time by this means; the rod is supported at its extremity, by resting upon the extremity of a lever *n*, the opposite end of which is moveable on a centre pin fixed in the column of the frame. This lever is supported by a second lever *i*, moving on a centre in a small standard erected

for it. The opposite end, *o*, of this lever is loaded with a heavy end, that will overbalance the lever, *n*, and rod *e*, and lift them up, so that the tooth of *e* passes clear over the teeth of the ratchet wheel, without interfering with them, and in this state the carriage is at rest. The end, *o*, of the lever *i* *o*, when the machine is mortising, is supported upon a ruler of iron *p*, *fig. 3*, which is fastened by screws to the side of the carriage *C D*. This supports the rod, *e*, to descend so low, that its tooth turns the wheel round at every revolution, and advances the carriage; but when it has proceeded the length of the intended mortise, the ruler gets beyond the heavy end of the lever *n* *o*, which drops down and relieves the screw from any farther motion, so that there is no danger of cutting the mortise longer than is proper.

A very ingenious part of this machine is the contrivance for giving it motion or stopping it at pleasure. The fly-wheel *I*, and also the pulley, *H*, for the strap, are fitted upon a round part of the main axis *E*, so as to slip round freely thereon, when the machine is to be at rest. When it is to be worked, the pulley and its axis are united by a wheel *R*, *fig. 1*, fitted on the axis by means of fillets, so that it is constrained to turn round with the axis, but has liberty of sliding along it. The latter motion is given to it by a lever, *V*, extending across the frame, to which it is connected at one end by a centre pin, and in the middle it has an aperture large enough to receive the centre piece of the wheel *R*, in which a groove is turned to admit the points of two screws *v*, *v*, which operating in the sides of the groove, confine the wheel endways upon its axis; but the wheel turns round without interference with the lever. The wheel, *R*, is formed conical upon its edges, and can be by the lever, &c. jammed to fit in a similar cone formed within the pulley *H*. In this state, the friction of the two conical surfaces is sufficient to turn the machine; but when the wheel, *R*, is drawn back on the axis, so that its conical edge is disengaged from the conical cavity formed within the pulley *H*, the fly-wheel slips upon the axis at the same time the cone on the back of the wheel, *R*, is jammed into an iron ring, *W*, firmly fixed to the frame. It is formed conical within, in the same manner as the inside of the pulley *H*, and when the wheel is jammed into it, fixes the axis motionless. This is a very proper provision, as the friction of the fly-wheel running so quickly upon its axis, when it is cast off, might be sufficient to move the machine slowly, and the momentum it acquires would, in addition to this, keep it in motion for some time; but the conical wheel being jammed in the fixed ring, *W*, as soon as it is withdrawn from the pulley, destroys the motion of the machine at once.

The chisels are provided with small teeth *r*, *r*, *fig. 6*, which are fitted into dovetailed notches formed in the blade of the chisel. These are called *scribers*: they have a sharp edge projecting a small distance beyond the inside edge of the chisel, and, therefore, in descending through the mortise, the scribes cut the sides of the mortise fair, and cut two clefts which separate the chip (which will be cut out at the next stroke) at its edges from the insides of the mortise, so that the chip comes out clear without splitting at the edges, and this makes the insides of the mortise as clean and smooth as possible. Each chisel has a piece of steel *t*, *fig. 6*, fixed on before the edge, by a screw which projects from the middle of it, and is screwed into the blade of the chisel: the upper end of the piece being received in a notch or groove formed in the chisel attaches it fast thereto. This piece, or nose, is for the purpose of clearing the chips out of the mortise as fast as the chisel cuts them; for though, in general, when the scribes are in proper order, the chips fall down through the block like pieces of pasteboard, yet it may happen that they will stick in, and then without this

nose-piece would clog up with the chips, so that the chisel could not be got down through them. The block is fastened into the carriage by means of a screw *r*, which has on the point of it a ring of the same dimensions as that on the screw of the boring machine, and is inserted into the impression made in the end of the block by that ring. There are three of these screws, for the purpose of holding one or more blocks at the same time. The centre screw is used for fixing one double or threefold block; or, the two other screws are used, when two single blocks are to be fixed in at the same time. The centre screw is then useless. By means of these screws, the true position of one end of every block is determined, so that it will fall exactly beneath the chisel *A*. The other end of the block is gauged into its place by stops: these are attached to a cross-bar, *1*, placed across the carriage, its ends being received into notches made in the sides, and these notches afford the means of fixing the bar at any place correspondent to the length of the block which is to be mortised. Against this cross-bar, the ends of the blocks are pressed by means of the screws *r*, *r*, and opposite to each is a sharp-edged steel ring to penetrate and hold fast the block: but to prevent it from turning round, on these two rings as a centre, each of the rings fixed on the cross-bar has two smaller rings inscribed within it, which also penetrate the wood, and thus fasten the block in the firmest manner. This is shewn at *fig. 5*. The gauges before-mentioned, for guiding the block to its true situation, are formed on a piece of iron *2*, which has two arms, *3*, *3*, projecting from it. These have other arms rising from them at the ends in a vertical position, and against these one side of each block is applied to make it vertical. A small piece of iron *4*, which is fitted upon two vertical pins *5*, *5*, and can slide up and down upon them, and fasten at any elevation by means of two clamp screws, forms the gauge for the height of the block, and is by these screws adjustable for blocks of different breadths. The two arms, *3*, of the piece *2*, are formed at the same distance asunder as the screws, *r*, in the front of the carriage, so that when one is set in the position for a block to be held by one screw, the other block will be at the proper place for the other screw. The adjustment for the different thicknesses of the blocks, is made by sliding the whole of the piece, *2*, endways, for which purpose the screw which fastens it to the cross-bar *1*, passes through a groove in the piece which admits this adjustment, and gives means of fastening it at any place corresponding with the thicknesses of the blocks.

The operation of the mortising machine is as follows: the block brought from the boring machine has the point formed by the screw thereof applied to the end of one of the screws at *r*, *r*, in the carriage of the mortising machine, and by screwing it tight, the block is fixed between its point and the double circle points before mentioned on the cross-bar *1*, and the stops situated on this bar guide the block to its proper position, which is, that the hole bored for the commencement of the sheave hole shall be vertical. The block being thus fixed, the handle, *s*, is turned till the hole is brought beneath the chisel *A*. The machine is now put in motion with the lever *V*, as before described, by jamming the wheel *R* into the cone within the pulley *H* of the fly-wheel. At the first descent of the chisels, they cut down through the whole depth of the holes previously bored, so as to cut a flat side to them. When they rise up, the eccentric, circle *b*, moving the bent lever and rod, *e*, moves the ratchet wheel *M* round one tooth, and advances the block a very minute quantity forwards from the fly-wheel, so that the chisels, in descending, cut a fresh space, and, in ascending, the block advances; and in this manner it proceeds with astonishing rapidity through the whole length of the intended mortise.

MACHINERY.

mortise. At this time, the loaded end, *o*, of the lever, *i o*, drops off the ruler fixed at the side of the carriage *C D*, and rises the levers *n* and *e*, so that the farther advance of the block is prevented. The attendant to the machine, as soon as he observes this, stops the motion by moving the lever *V*, and he takes care to do it at the instant when the chissels are at the highest point, which is effected by a dextrous movement, for the fixed cone, *W*, stops the machine instantaneously.

The finished block is now removed, and a fresh one put in the handle, *s*, turned back to return the carriage, and bring the block to the proper point, when the machine is started, and proceeds as before.

Three mortising engines of different dimensions are used at the mills, corresponding with the different sizes of blocks to be manufactured. The smallest and largest of these is what we have described in our *Plate*. The intermediate machine was made before the others, and with some difference in its construction, though none in its effect. The motion of the sliding frame for the chissels is communicated to it by means of a long working beam or lever, extending the whole length of the frame at the top of it. At one end, it is united by a connecting rod with the chissel frame; and at the other, it is fixed to an axis, which is supported by the framing, and which forms its centre of motion. A connecting rod is joined to it in the middle of the beam; and the lower end of this is worked by a crank, formed in the middle of the main axis, which is situated in a direction perpendicular to that which we have described, and is supported in the framing. It is provided with the cone for casting off the movement. This machine operates equally well with the others, from which, indeed, it does not differ in any essential point. But the movement of the machine we have drawn, is that which is most complete, and less subject to violent strain in any part. The engine with the beam acts with surprising rapidity, as it makes upwards of 400 strokes *per* minute, at every one of which it cuts out a chip from each mortise as thick as pasteboard. Its movement is so extremely quick, that the chissels cannot be distinctly seen when it is at work, and the mortises are observed to lengthen, and chips fall out without any evident cause. The blocks, being thus mortised, have their angles sawn off, as a preparation to giving them their elliptical figure, by

The Corner Saw.—This is a circular saw, shewn at *figs.* 8 and 9 of *Plate IV.* where *fig.* 7 is a plan of the bench, *fig.* 8 a front elevation, and *fig.* 9 an end section. In these, *A* is a circular saw, fixed upon a spindle *a*, mounted in an iron frame *B*, like a lathe spindle, and turned by a band round the pulley *C*. The block is placed upon an inclined table *D*, which presents it to the saw, so as to remove a proper portion of the angle, and prepare it for the shaping engine, which forms the exterior surface of the block. The block lodges against the ledge, *E*, of the table, which guides it whilst it is sawn, by keeping it to the same distance from the saw. It is accommodated for blocks of different dimensions, by placing wooden rulers of proper thicknesses against the ledge *E*, to bring it near to the saw. In one of these machines, the ledge, *E*, is fitted with connecting bars in the style of a parallel ruler, so that it can be fixed at any distance from the saw, but always parallel thereto. The saw is fixed on a chuck, which is attached to the spindle for sawing, so that it can be quickly removed to sharpen the saw.

The Shaping Engine.—The shaping engine consists of a double wheel, called its *chuck*, in which ten blocks are fixed at once. These being turned rapidly round, a gouge is fixed so as to intercept them, and form their external surfaces to segments of the circles in which they all revolve. This is the general principle of the machine. Its particular

construction is explained by *Plate VI.* where *fig.* 1 is an elevation; *fig.* 2, an edge view; and *fig.* 3, a plan. The detached figure parts we shall soon explain. The separate figures at *X* and *Y*, in the corner of the plate, are introduced to explain the state of the block when it is brought to this ingenious machine, and to shew also the change made upon it. *Fig.* *X* is a front view, and *Y* an edge view of a double sheave block. The outlines shew the form of it when finished in the shaping engine, and the dotted lines its form before it is put into it. Thus the four angles are shewn as cut off in *fig.* *X* by the corner saw, preparatory to giving it the elliptical figure it is to have. The other view shews nothing cut off by the corner saw, the whole alteration being made by the shaping engine. This figure also shews the state of the mortises.

The machine, as before-mentioned, contains ten blocks, which are all shaped at the same time, being fitted in a large wheel, or rather, between the circumference of two wheels *A A* and *B B*, having a common axis *C C*. The blocks are shewn at the letters *E, E*; and the plan, *fig.* 3, explains the manner in which they are held between the wheels by a screw, *a*, having a steel ring fitted upon the point of it, which is exactly the same in all respects as the ring on the point of the screw of the boring machine; and the ring of the screw *a*, being inserted into the impression made in the end of the block, secures one end; the other is retained by a ring, *b*, of the same dimensions, containing two others within it, which enter the impression made in the other end of the block by the double rings in the carriage of the mortising machine, to which they are exactly a counterpart. The double ring, *b*, is formed in the end of a short spindle, fitted in a socket through the rim of the great wheel *A*, exactly opposite the screw *a*, and has on the outside of the wheel a small toothed wheel *d*. The screw, *a*, being tightened up by a winch, the block becomes fastened in between the point of it and the spindle *b*, as it were in a lathe. The compound wheels *A A, B B*, or more properly the chuck, as we shall in future call it, being thus filled with blocks, has a rapid circular motion given to it by means of an endless rope encompassing the pulley, *F*, on the main axis. Now it is evident that a cutting tool, being presented to the blocks as they revolve, will form their exterior surfaces to segments of circles, of the size of that which they revolve in. This tool, which is a gouge, is held in a sliding rest, shewn separately in *figs.* 4 and 5, and is also seen in the other figures. It consists of a dove-tailed slider *G*, accurately fitted into a groove, which is part of a frame *H*, that is attached to a long metal bar *I K*, curved to a segment of a circle; see *fig.* 1. At one end, *K*, it is fitted on a centre piece, fixed in a cross-bar of the frame, exactly beneath the centre of the axis of the chuck: the other end of this bar, which may be called the radius, rests upon a part of the framing *L*, which is curved to a circular arch, and on this the radius rests, as it sweeps on its centre from one side to the other of the machine. The slider *G*, for the gouge *g*, is advanced towards its work by a lever *M*, having a handle *m*, *figs.* 3 and 4, at one end; and the other is fitted on a centre pin *n*, fixed in a projecting part of the frame of the groove *H*. To the middle of the lever a short connecting bar, *b*, is jointed, and communicates the power of the lever to the slider *G*, and consequently advances the gouge *g*, which is held in the end of it, towards its work: but the quantity of this advance is determined by a roller *e*, the axis of which is fitted in a socket attached to the slider *G*: it bears against a guide or pattern ruler *N*, which is supported on two pillars from the frame of the machine. The pattern ruler has such a de-

MACHINERY.

gree of curvature, as shewn in the plan, that when the roller, *e*, of the slider, *G*, is kept in contact with it by a pressure on the handle, *m*, towards the machine, and the whole slide rest is swept along its curved rest *L*, the edge of the gouge, *g*, will describe that curve which the surface of the block is intended to have, as shewn by the dotted line at *E*. The manner of action in this machine is easily gathered from what we have said. The chuck being filled with blocks, as before related, the sliding rest is moved quite to the end of its slider *L*, and in this state the machine is put in action. The workman now holds the handle, *m*, in one hand, and the long handle, *R*, (which is attached by a joint to the frame *H*,) by the other hand: with the former he presses towards the machine to keep the roller, *e*, in contact with the ruler *N*, and by the latter he sweeps the gouge slowly and steadily from one side of the frame to the other. In this circuit, the edge of the gouge removes the angles of all the ten blocks at once, reducing them on the outside to the figure of the dotted line *E* in the plan, which, as before explained, is determined by the curve of the pattern ruler. This being done, the machine is stopped, and it is necessary to turn all the blocks round one quarter upon their respective axes to present another side outwards, that it may be shaped to its proper curve in its turn. This is accomplished in a very ingenious manner. Each of the small spindles, *b*, has, as before stated, a small wheel, *d*, fixed upon it, and to every one of these an endless screw is adapted. The axes of all these screws marked *f*, tend to the centre of the chuck, and each has a small bevelled cog-wheel upon it; and all these are turned by one large bevelled wheel *O*, which is fitted upon the main axis, but slips round freely thereupon. It has a pin projecting from a part of its circumference, which is detained by means of a stop *Q*, *fig. 1*, jointed to the frame at the lower end, and forked at top, to catch this pin when it is moved on its joint so as to approach the wheel; but when thrown back by a spring in its joint, into the position of the figure, it is out of action. When the blocks are to be turned round one quarter, this stop is pressed towards the wheel, and the pin, by turning the chuck round, catches in the forked top of it, and prevents the wheel from turning. The workman now, by taking hold of the chuck, turns it round four times, as he determines by observing a mark made upon one part of the run of the chuck coming opposite to some part of the framing. In these four turns of the chuck, the centre wheel, *O*, remaining stationary, the blocks are, by means of their endless screws *f*, turned round one-fourth of a circle, and the next face of each block is turned outwards to be subjected to the action of the gouge. But the sides, now exposed, being those in which the mortises are made, are of a more rapid curvature, being of an elliptical figure, as shewn at *X*, in the corner of the plate, while the former was only slightly rounded. To give this difference of curvature, a new moulding ruler, *N*, is employed. This is fixed immediately beneath the other one, as shewn by *figs. 1* and *2*, and the roller, *e*, of the slider, *G*, is adapted to act upon either; its axis being let down in its socket, and retained at the proper level to work with either, by a clip or clasp (not shewn in the figures,) which enters either of the two grooves formed round in the spindle of the roller; and for the purpose of elevating or depressing the roller, its spindle has a head, *S*, fixed on the top of it. The roller being now shifted to the proper pattern ruler and all the blocks, the turning of these sides is performed in the same manner as the first, but, of course, giving it a different curvature corresponding to the difference of the two moulding rulers. The machine is now stopped, the blocks shifted to another

quarter, the guider roller, *e*, returned to its first ruler, because the machine is now to form those sides of the blocks opposite to what were first done, and therefore the same curve. The chuck being again set in motion, the third side is turned. The movement is now stopped, the roller, *e*, shifted to the same ruler as for the second side, and the blocks being turned round another quarter, the last side is finished, and they are removed from the machine to make way for another set.

This ingenious machine is adapted to receive blocks of different dimensions by the following means: the length of the blocks are allowed for, by placing the wheels, *A A*, *B B*, of the chuck at a greater or less distance asunder upon their axis *C*. This is done by the five screws, *T*, which unite them. The wheel, *A*, is fixed fast to its axis, and the other slides upon it, to regulate their distance; the screws, *T*, have nuts upon them, both within and without the wheel *B*, so that they hold it quite firmly at the intended distance from the other. The next adjustment, dependent on the size of the block, is that the edge of the gouge shall describe its curve at the proper distance from the centres of the several blocks, to make them of the intended dimensions. This would be adjusted by placing the pattern rulers, *N*, at a greater or less distance from the blocks; or, what has the same effect, altering the distance between the centre of the roller *e*, which applies to the rulers, and the edge of the gouge *g*. For this purpose, the socket for the spindle of the roller is fitted into a groove in the slider *G*, and is regulated by a screw, *P*, at the end of the slider. The trial is made by setting the gouge opposite the centre of the block, as in the plan, and turning the screw *P*, until the edge of the gouge very nearly touches the block in the centre, because it is intended only to take off the corners of the block, little or nothing being removed from the middle. This adjustment is necessarily made every time the gouge is removed from the slider to sharpen. The gouge is fastened into the holder, at the end of the slider *G*, by means of a screw, as shewn in *fig. 5*.

Three moulding rulers are shewn in the figures, though we have only explained the use of two. Double and single sheave blocks of the same lengths have both the same curvature on the edges in which the mortises are, and therefore they may be shaped indifferently from the same pattern ruler: but considering them in the other direction, *viz.* that in which the plan exhibits them, the gouge is required to traverse its curve at nearly twice the distance from the centre of a double block, to that required for the single sheave; and this is effected by providing an additional pattern ruler for the single blocks: therefore, in the machine as represented, one ruler is adapted for shaping the edges of either single or double blocks, a second for the outsides of the cheeks of double blocks, and a third for the cheeks of single blocks: all the three rulers can be quickly removed from the machine, and others of a different curvature substituted, being only fixed by two screws to the pillars which rise from the rest *L*; and a great variety of these patterns are provided to suit all kinds of blocks, of which an amazing number of shapes are in use in the navy. As this shaping engine is a machine which would be very easily applied to other purposes, it may not be uninteresting to describe the manner of forming a pattern ruler to shape any curve. It is done experimentally by choosing such a block as is of a proper figure, or forming one by hand to the intended curvature, and fixing it in the chuck; then substituting any blunt tool in place of the gouge, and fixing a sharp tracing point on in the end of the centre pin of the roller *e*: a piece of board is fixed in place of the pattern ruler. The tool is

now

MACHINERY.

now applied to the block fixed in the chuck; and being kept in contact with it, while the sliding rest is swept from one end to the other, the point in the centre of the roller traces a curve upon the board: the block is then to be removed, or turned out of the way. Now by placing the sliding rest successively at different parts of its sweep, and thrusting the slider, G, towards the machine by its lever M, the tracing point will describe straight lines upon the board, all tending to the centre of the machine, or rather to the centre, K, of the radial bar; and as many of these being made at short intervals as is thought proper, the board is removed. A pair of compasses being now opened to the exact radius of the roller *e*, this distance is set off, from the traced curve, upon every one of the radial lines, thus transferring the curve as much nearer to the centre as the semidiameter of the roller. A curve is now drawn through these points, and the board being cut to it, will have the curve desired, and may be used as a pattern to cast a metal ruler from, which being fixed in the same points as the board was, will shape the blocks to the form of that which was employed as the pattern for it.

Three shaping engines are employed for blocks of different sizes: the largest, which was last made, is that we have described; the smaller one is very nearly like it; but the intermediate size, like the mortising machine, is of a less perfect construction, and shews the progress of invention: it holds but a small number of blocks, and these are turned round on their axes, one by one, by the workman. A circular plate, with four notches in its edge, which are caught by a click, is the gauge for setting them correctly to one-fourth of a turn each time they are shifted. Even this machine is a very excellent one for the purpose, though greatly improved in the second and third, which were made by the introduction of the wheels and screws for setting all the blocks together, which is a most ingenious contrivance.

The large machine has a contrivance, very similar to the mortising machine, for checking its motion as soon as the movement is cast off; for otherwise the momentum of the chuck loaded with blocks would be considerable. The machine in our plate is represented with a wheel, V, upon it, which is surrounded by a brake or gripe: this is relieved from the wheel by a spring, when the machine is in motion; but when the workman presses a lever (omitted in the drawing), it encompasses the wheel by its gripe, and causes a friction, which quickly stops the machine. The framing supports a number of iron bars, which enclose the chuck as it were in a cage. This precaution is very necessary to the security of the workman; for if the blocks should get loose, as has once happened, they would be thrown by the centrifugal force with the velocity of bullets, and might do serious injury. The accident alluded to was occasioned by one of the wheels of the chuck cracking in the rim, so as to let loose the blocks, and they all flew out behind the machine, passing through a window, into the steam-engine house, where they struck the governor or regulating balls of it, and broke them in pieces. It is singular that, in passing through the window, all the blocks followed each other through the same pane of glass with great violence.

Scoring Machine.—We now come to the last machine in the series: this is the scoring machine, which forms the score round the block for the reception of the strap or rope, by which it is suspended in the rigging of the ship. The score is a groove, deep enough at the ends of the block to receive one-half of the rope or strap, but is diminished to nothing where it crosses the pin of the block. The machine is represented in *Plate VII.*, where *fig. 1* is a hori-

zontal plan of the upper part of the machine, and *fig. 2* a plan of that part containing the blocks; *fig. 3* another plan taken immediately below the former; *figs. 4* and *5* are elevations of the machine taken in two directions at right angles to each other. Two blocks, in the state they are finished by the shaping engine, are scored at once by this machine: one of these is marked Y, the other is dotted. The groove is formed by a circular cutter A B, situated exactly over each block: these cutters are circular wheels made of brass, and formed round upon the edge. In two opposite points of the circumference are two openings, as *a, a, fig. 4*, in which cutters with round edges are fixed to project a little beyond the rim of the wheels, in the manner of a plane iron; and they cut the wood in exactly the same manner, except that they move in a circle instead of a straight line. These cutters are both fixed on one spindle C, which is turned by a band round the pulley D, in the middle of it. This spindle is mounted in a frame E E F F, *fig. 1*, which moves on an axis, F F, centred in the frame, (see *fig. 4*.) so that the spindle has liberty of ascent and descent by the handle H, but always keeps parallel to itself. The blocks are held in a frame erected upon a strong plate G, *fig. 5*, and shown separately in *fig. 2*, which is wings on the points of two centre screws, *b, b*, in the manner of an axis: it is moved by the handle I, and governed by a pendulum K. By this motion, all parts of the blocks can be presented to the cutters: each of the blocks is fastened in the frame by means of two pins, *d, d*, erected from the plate G, the block is pressed with sufficient force to hold it in between these by a screw *l*, which operates upon a clamp *e*, connected by a joint with the lower plate G. The upper end of this clamp has a half ring formed in it, which catches in the impression made in the end of the block by the preceding machines, and thus fixes it, so that its centre comes beneath the cutter; and as the block is shaped equally on each side of its centre, it will assume the true position, by being forced between the two pins *d, d*, without regard to the size of the block. The frame, E F, has a curved piece of iron fixed beneath it, which is formed so as to inclose the pulley, D, on the lower half, as close as it can be not to touch, and is therefore concentric with the axis C. This piece of iron comes down upon the edge of a metal plate L, which is the pattern for scoring the block, as it regulates the depth to which the score shall be excavated, being nothing at the centre of the block, and deep enough at the ends to bury half the strap. The action of this machine is simple. The blocks being fixed as before mentioned, the workman takes one handle, H and I, in each hand, and by the upper one keeps the curved iron always in contact with the pattern, L, beneath it: at the same time, by depressing the handle I, the blocks are inclined, so that they travel beneath the cutters A, B, to form the scores from their centres to the ends of them, the two pins *d, d*, admitting the cutters between them quite to the ends of the blocks, and in depth as much as the pattern, L, allows the cutters to descend beneath the surfaces of the blocks. Now it will easily be seen, that by raising up the handle I, the other ends of the blocks might be scored in the same manner, and so indeed they are in the first machine that was made, and which is still in use at Portsmouth: but the objection to the method is, that the cutters cut against the grain of the wood, so as to be rough, in the same manner as when a carpenter planes the edge of a board obliquely to the direction of the grain, if he planes from one end it will cut smooth, but in the other direction it will cut ragged and rough. To avoid this in the machine before us, the plate G, to which the blocks are immediately fixed, is united to another plate M beneath it, by

MACHINERY.

a centre pin *m*, which is exactly beneath the pattern *L*, and also in the middle between the two blocks and cutters; on this as a centre, the upper plate, *G*, turns round, and is detained by a spring catch *n*, which is fixed to the lower plate, and falls into a notch made in a projecting part of the upper plate *G*, when the two blocks are in their proper position. The first quarters of the scores of two blocks being cut as before described, the workman relieves the catch *n*, and turns the plate, *G*, half round on its centre, when the catch again detains it in this position, by which the blocks are reversed, having exchanged situations, and their finished ends are outwards; consequently, the other ends, where the screws *l, l*, are, are beneath the cutters; the handle *l* being, therefore, depressed as before, cuts the second quarter of the score, and in the same manner as the first, being in the proper way of the grain of the wood to cut smooth. This completes one half, and the blocks are taken out to be turned the other side upwards, to cut the scores in them by a repetition of the same process as we have described. The axis of the frame, *E F*, has a lever proceeding from it behind, which is loaded with a sufficient weight to counterpoise the weight of the frame and cutters, giving them a constant tendency to rise upwards, and thus keep out of the way when the handle is left to itself. The pattern *L*, which determines the depth of the score, and therefore depends upon the curvature of the block, can be quickly removed from the machine, to make way for any other shape being fixed to the plate, *G*, by only two screws. A great variety of these patterns is required, as well as for the shaping engine, and their curvature is determined by the same means as we have before described of that machine.

The operation of scoring is the last which is performed by machinery upon the shells of the blocks, which are now completely formed, and only require to be rasped and filed to a smooth surface, which the machines will not always do, though they cut them perfectly correct to the intended forms; but the wood is not always so hard and perfect in its texture as to make them smooth, small pits being left in various parts, which require the aid of files and rasps to remove them; though, by a little labour of this kind, they are made as neat as can be wished. The machines will, when their cutters are in order, and the wood of good quality, cut as smooth as any thing can be expected. Of this we are convinced by having seen the performance of a set of working models of these machines, which we hesitate not to say are the most perfect and elegant models that have ever been made of any kind of machines: they are about four times the size of the drawings in our plates, and are all placed upon one large table, so as to exhibit the whole of the operations, as they succeed each other, at one view. A very elegant model of a steam-engine, made on Mr. Maudslay's pattern, actuated the whole. These models are deposited in the Admiralty house, Westminster. They operate in a more precise manner than the large machines, their cutters being kept exceedingly keen, and the wood they work upon being of a harder and better kind. The blocks at Portsmouth are made of elm, which is a very proper wood for them, not being liable to split: the sheaves, as we have before-mentioned, are made of *ignum vitæ*.

In the operation of dressing the blocks by hand, we must notice a plane, for making the insides of the mortises perfectly smooth and flat; for though the mortising engine will, when in very good order, cut as correctly as possible; yet it is advisable to plane the insides, to be certain that they are not rough, for that would occasion a great friction at the sides of the sheave. The plane is of the same form as a carpenter's, but is made of brass and very thin, that it may enter

the mortise. It is fixed projecting horizontally from the edge of a work-bench, and the workman, taking the block by its end, inserts the end of the plane into the mortise, and thrusts it forwards. The plane cuts a shaving from the inside of the mortise, in a direction across the grain, and thus at two or three strokes finishes them, and they are ready for putting together, which completes the blocks. As connected with this subject we shall describe the

Machine for making dead Eyes.—This is a very ingenious and complete machine, and it forms the whole of the article at once. The pieces of wood being sawn to the size, have the holes bored through them in the boring machine, for the reception of the rope which is to be reeved through them. Two of these holes are equi-distant from the centre of the block of wood; and by means of these two holes, it is fixed in the machine, which shapes and scores it at twice fixing. This is represented in *Plate VII.* where *fig. 6* is a plan of the whole machine, and *fig. 7* an elevation in front. The frame or bench sustaining it, is omitted, only the working parts being shewn. It is a lathe, to which proper mechanism is added. *A B* is its spindle, supported between the standards *Y, Z*, and *C* the pulley for turning it by a hand *D*. *Fig. 6* is a chuck, screwed to the end of the spindle: this chuck has a double screw, *a b*, in it; that is, a right and left handed screw, which operates upon two sliders, carrying two round pins, *x, x*, which project from the face of the chuck: one of these sliders is moved by the right hand part of the screw, which is the end *a*; and the other by the left hand part, which is the end *b*; and the screw being retained by a collar in the centre of the chuck, the two pins, *x, x*, with their sliders, mutually advance or recede, when the screw, *a b*, is turned with a wrench applied to the square ends *a* or *b*, *fig. 6*. By means of these pins, the block, *f*, is readily fixed to the chuck *D*. The screw, *a b*, is turned till the pins, *x, x*, are at the same distance asunder as the two holes in the block *f*, which is then hung on the pins, and the screw being turned, forces the two pins farther from the centre, and thus fastens it firmly to the chuck; and as the pins are always equally distant from the centre, they chuck it always truly. The turning tool, which is a gouge, is applied by a sliding rest, and apparatus of the same kind as that of the shaping engine. *E* is the circular iron rest on which the tool sweeps, and is supported to bear the pressure of the work. *F* is the radius bar, turning round on a centre pin, fixed in the frame immediately beneath the work, in the line of the spindle; and this radius is in one piece with the frame *H*, which is the foundation of the sliding rest. This consists of the dove-tailed slider, *G*, fitted into a groove formed on the top of the frame *H*: this slider is advanced to its work by the lever *M*, which has a handle, *m*, at one end, and the other is fitted on a centre pin, *n*, fixed in an arm projecting from the frame *H*. *N* is the shape or pattern ruler, supported by two columns, *O, O*; and is the roller which applies to the shape when the handle, *m*, is pressed towards the machine, as shewn by a dotted circle in *fig. 6*. The whole rest is swept round on by *E*, a handle similar to that of the shaping engine, but no part of which is shewn in these figures. The angles of the block are removed by the corner saw before it comes to the machine in which it is chucked, as before-mentioned, and then the spindle, *A B*, is put in motion. The workman, by the two handles, as before explained, of the shaping-engine, sweeps the tool one quarter round on the centre of its radial bar, *F*, and the roller applying to the shape, *N*, gives the dead eye, *f*, its intended curvature. The machine being stopped, the dead eye is removed from the chuck, and reversed; the other side being presented

to the tool is shaped in the same manner: the score now remains to be cut round its circumference. If this was merely a groove all round, it would be easily turned by a gouge, but custom has established, that it shall not continue quite round the dead eye, but have one point, (where the ends of the strap are to unite,) left solid. This is shewn in the plan *fig. 6*, and also in the other view, *fig. 7*, by the dotted line, *n*, being the solid part. This being the form of the score, it requires some particular mechanism to cut it, which is effected in this manner; a spindle, *P*, with a cutter, *Q*, similar to the scoring engine, is mounted in a frame, *R S*, which moves on a centre at *S*, so as to approach or recede from the work at pleasure. The spindle has a very rapid motion given to it by a band passing round the pulley *T*, and the cutter, being applied to the work, excavates the score as the block and spindle are turned round. The depth to which it is permitted to cut is determined by a roller, *d*, situated at the end of a rod, which is fitted on the axis, *S*, of the frame *R S*, and attached firmly to the frame by an arch *V*; in which is a groove to receive a clamp screw, which gives the means of fastening it at any point, and the roller then becomes a part of the moving frame *R S*. This roller applies itself to a pattern, or shape-wheel, *W*, fixed on the spindle, and turning with it. Its figure is circular, except a projecting knob on one side, *w*, as shewn by the dotted lines in *fig. 7*.

The manner of using this scoring apparatus is as follows: the shaping being performed as before described, the motion of the spindle is cast off: the workman now goes to the opposite side of the machine, and taking hold of the frame, *R S*, by one hand, and the pulley, *C*, of the spindle by the other, then applies the cutter (which before hung back out of the way), at the same time turning the work slowly round by its pulley: this cuts out the score, the pattern-wheel determining its depth, and the projecting part, *w*, of the pattern-wheel, when it comes round, lifts the cutter out altogether, leaving the solid, or unformed part of the score at *n*, as we have before described.

This machine readily adapts itself to receive different sizes: the two pins *x, x*, first mentioned in the face of the chuck *D*, screw into the sliders of the chuck which are moved by the double screw *a b*, and can be removed to put on any size corresponding with the size of the holes bored through the dead eye: these pins are made hollow, to avoid unnecessary weight in the moving parts. The screw, *a*, in the chuck will (as before-mentioned) expand the pins to hold any sized block. The screw *r*, at the end of the slider, regulates the position of the roller which applies to the shape *N*, and thus adapts to the thickness of the dead eye. The operation of this adjustment will be understood by referring to the shaping-machine. The shape, *N*, is readily changed, to make different sizes, by introducing others of a different curvature: for this purpose, it is only held on the pillars *O, O*, by notches, as shewn in the plan, and nuts being screwed upon it to hold it fast. The score is always in the middle of the dead eye; and, therefore, for different thicknesses, the cutter, *Q*, must be shifted endways: this is done by sliding the whole frame, *X*, supporting the centres, *S*, on which the frame, *R S*, of the spindle moves as a centre; the screws, *t, t*, which hold it, are fitted in grooves to admit of this motion, and the pattern-wheel, or shape *W*, as well as the roller, *d*, which applies to its circumference double the necessary width, to allow this variation, without losing their bearing. The projecting part, *w*, of the pattern-wheel, consists of an iron bridge, screwed on to the rim of the wheel: it is made very light, and has a balance weight on the opposite side of the rim to balance its weight; for, if this was not attended to, the rapid revolution of any unbalanced weight would, by its

centrifugal force, acting successively on all sides, cause a tremor of the whole machine, and a great wear and friction on the centres of motion; but when truly balanced, the motion is pleasant and equable.

MACHISCHEVO, in *Geography*, a town of Russia, in the government of Tobolsk; 36 miles W. of Ischim.

MACHLIS, in *Natural History*, a name used by Pliny and some of the old authors, for the elk, and also for the rein-deer.

MACHONOWHA, in *Geography*, a town of Poland, in the palatinate of Braclaw; 60 miles E. of Braclaw.

MACHRIANICK BAY, a bay of Scotland, on the W. coast of Kintyre. N. lat. 55° 27'. W. long. 5° 43'.

MACHSA, a town of Arabia, in the province of Yemen; 25 miles E.S.E. of Zebid.

MACHUA, a town of Hindoostan, in the circar of Sirowy; 20 miles N. of Jalour.

MACHUL, an instrument of music among the Hebrews: Kircher apprehends that the name was given to two kinds of instruments, one of the stringed and the other of the pulsatile kind. That of the former sort had six chords. Though there is great reason to doubt whether an instrument requiring the aid of the hair-bow, and so much resembling the viol, be so ancient. The second kind was of a circular form, made of metal, and either hung round with little bells, or furnished with iron rings, suspended on a rod or bar that passed across the circle. Kircher supposes that it was moved to and fro by a handle fixed to it, and thus emitted a melancholy kind of murmur.

MACHYNLLETH, or MACHYNLLAETH, in *Geography*, a market town in the hundred of the same name, in the county of Montgomery, North Wales, is situated at the conflux of the rivers Dulas and Dovey, 37 miles distant from the county town, and 207 from London. It has a claim to high antiquity, being generally supposed to have been a Roman station, named the Maglona of the Itinerary: many ancient coins have been discovered in the vicinity. In this town, Owen Glendwr, in the year 1402, when, from repeated successes, he was in the meridian of his glory, assembled the estates of Wales, and held a parliament; by which his title to the principality was solemnly acknowledged, and he was formally inaugurated sovereign of Wales. On this occasion he narrowly escaped falling a victim to the hatred of his brother-in-law Dafydd Gam, who attended the assembly with intent to assassinate him; but his design was timely discovered. An old house, now divided into tenements, is shewn as being that in which the parliament was holden. The inhabitants of this town are chiefly employed in handicraft business; that of tanning being carried on to a considerable extent, as is also the manufacture of flannel, and of what are provincially termed webs, and Welsh plains or cottons. These are a coarse sort of thick white cloth, made in pieces from ninety to one hundred and twenty yards in length: this article formerly constituted a portion of the export trade, but latterly has been appropriated to clothing the army, and for home consumption. Seven annual fairs are held here, and a weekly market on Wednesday. The population of the parish, which includes, with the town, the townships of Is Carreg and Uwch Carreg, was, in the year 1801, returned to parliament as 1825, occupying 372 houses. Pennant's Tour in Wales. Carlisle's Topographical Dictionary of Wales.

MACIAS, EL ENAMORADO, in *Biography*, a Spanish poet, celebrated as one of Love's martyrs, was born in Galicia towards the close of the fourteenth century, and educated in the household of the famous Henrique de Villena, master of Calatrava, who was very friendly to him.

He fell in love with a damsel of the same household; the passion was mutual, but effectually concealed from all other persons, and when Macias was absent, the master gave her in marriage to a knight who resided in Porcuna. Macias on his return grew desperate, which occasioned his imprisonment at Arjonilla; here he employed himself in making verses on his mistress, some of which were carried to the husband; who, in a fit of rage, mounted his horse with a spear and shield in his hand, rode to the prison, and slew the unfortunate captive as he was singing a song in honour of his love. Other accounts say that he bribed the keeper of the prison to untile a part of the roof, and slew him from above. He was buried in the church of St. Catalina, at Arjonilla, and this short epitaph was inscribed on his tomb "Aqui yace Macias el Enamorado." The lance was preserved upon his grave, and some Spanish verses written under it. In such cases, says the biographer, the Spaniards generally take part with the husband; but Macias was a poet, and the poets took up his cause. Their works are full of allusions to this story. The song which occasioned his murder is preserved in the *Escorial*, and has been printed by Argote de Molina in his "Nobleza de Andalucia," and by Sanchez in his notes upon the marquis of Santillana's letter. *Gen. Biog.*

MACIECOW, in *Geography*, a town of Poland, in the palatinate of Chelm; 40 miles E. of Chelm.

MACJEJEWICE, a town of Poland, in the palatinate of Lublin; 44 miles W.N.W. of Lublin.

MACIGNO, in *Mineralogy*, the Italian name of a rock, which is employed for the purposes of building at Florence, and throughout Tuscany, where it is said to constitute entire mountains of a stratified structure. Patrin, who calls it "une pierre marneuse et micacée," has given the following account of this useful stone. There are two varieties of macigno with regard to colour; one of them, called *pietra bigia*, is of a greyish-yellow; the other, denominated *pietra serena*, of a blueish-grey colour. This latter, of which most of the houses of Florence are built, has the inconvenience of becoming black when exposed to the air, and at length to decompose. The *pietra bigia*, which contains much oxyd of iron, possesses greater solidity, and is less acted upon by the atmosphere; it is calculated for the exterior of buildings, while the *pietra serena* should only be employed for the interior.

The upper strata in the macigno quarries are more clayey than the others; they resist the action of the fire sufficiently well, so that they are made use of for the construction of furnaces and hearths. The same hills exhibit strata or beds, some of which are of a less solid texture than the macigno, and appear often to be nothing but indurated clay; these layers are called *bardellone*. The others, on the contrary, are much harder than macigno; they are of a white colour, and bear the name of *pietra forte*. This latter is the stone which is employed for paving the streets of Florence.

Ferber is of opinion, that the two kinds of macigno, together with the *bardellone* and the *pietra forte*, are varieties of one and the same rock, in which clay, calcareous earth, and mica, are by turns predominating.

The *pietra forte* varies as much as the macigno with regard to colour; it is often greyish or blueish-yellow, and sometimes these two colours are even united in the same piece.

In the quarry of Campora, situated two miles from Florence, and yielding the stones with which the streets of Florence are paved, the *pietra forte* is disposed in horizontal layers that have only a few inches in thickness, and are sometimes separated from each other by similar layers of *bardellone*; and not unfrequently a crust of calcareous spar,

of about a line in thickness, intervenes between the latter and the *pietra forte*. Ferber supposes, that it is this calcareous substance which, by penetrating into a layer of *bardellone*, converts it into *pietra forte*.

Patrin adds, that this stone exhibits a remarkable appearance in its interior structure; which is, that it divides into rhomboids separated from each other by disseminations of calcareous spar. This author is of opinion, that the calcareous and argillaceous particles have been deposited at the same time; that afterwards a separation has taken place by elective attraction, and that the calcareous particles, tending to arrange themselves in rhomboidal forms, have imparted to the *pietra forte* the same character which is communicated by them to the sandstone of Fontainebleau.

It is in these macigno hills that the beautiful varieties of marble, exhibiting landscapes, ruins, &c. and known by the name of *Florentine marble*, are found. See *MARLE*.

The above is all that is known of the nature of the stone of the neighbourhood of Florence; it should, however, be observed in this place, that the *bardiglione*, properly speaking, appears to be a different substance from that described by Patrin and Ferber under the name of *bardellone*; the former being the anhydrous sulphate of lime, (anhydrite and wülfelspat of Werner,) on which count Bournon has given a memoir in vol. i. of the *Transactions of the Geological Society*.

MAC-INTOSH, in *Geography*, a county of America, in the lower district of Georgia, between Liberty and Glynn counties, on the Altamaha river. It is divided into four towns, and contains 2660 inhabitants; of whom 1819 are slaves.

MACK, in *Agriculture*, a provincial term sometimes applied to a sort or kind of grain, or breed of cattle or live stock.

MACKALLY, in *Geography*, a town of Bengal; 35 miles S.S.E. of Moorshedabad.

MACKENZELL, a town of Germany, in the bishopric of Fulda; nine miles N.E. of Fulda.

MACKENZIE, Sir GEORGE, in *Biography*, an eminent Scotch lawyer and miscellaneous writer, was born of a noble family at Dundee in 1636. He studied at the universities of Aberdeen and St. Andrews, and finished the usual course of classics and philosophy; at the age of sixteen he was sent to Bourges in France, where he passed three years in the study of the civil law. On his return to Scotland, he was admitted to the bar, and soon became distinguished for his talents as a pleader. He was appointed, in 1651, the advocate for the marquis of Argyle, impeached of high treason, and spoke with so much fervour and boldness in behalf of his client, as to draw down upon him a reprimand from the bench. This, however, did not stop his career, and in a short time after he was raised to a seat on that bench in the criminal court. A piece of service which he rendered to the court in 1674, by effecting a reconciliation between the lords of session and the faculty of advocates, caused him to be knighted, made king's advocate, and one of the lords of the privy-council in Scotland. In the contentions of that period the post of king's advocate, which is analogous to that of attorney-general in England, was equally important and arduous. Sir George, who had embraced the doctrine of passive obedience, exerted so much zeal in his new office, that he obtained from the covenanters the title of the "blood-thirsty advocate, and the persecutor of the saints of God." Notwithstanding this, he introduced into the form of criminal trials several alterations favourable to the accused, and so far from endeavouring to extend the power of his office, he considerably retrenched it. Like
other

other officers of the same rank, he has been charged with endeavouring to stretch the law of treason, especially in the cases of Baillie of Jerviswood, and the earl of Argyle, the sentence against the latter of whom was rescinded by act of parliament in the reign of William and Mary. When James II. abrogated the penal laws, sir George, who was sincerely attached to the Protestant religion in the episcopal form, resigned his office. The king, however, gladly restored him to his post, when he was convinced of the necessity of pursuing different measures, and he firmly adhered to his master's interest in the subsequent change. He opposed in council the proposed address from Scotland, to the prince of Orange on his landing in 1688, and he wrote also a memorial to that prince exhorting him to adhere to the terms of his declaration. At the convention of the estates he argued very warmly against the declaration of a vacancy in the throne, and the election of William for sovereign, and when he found his opposition ineffectual, he retired to Oxford, where he was admitted a student. He died in London in 1691, and was interred with signal funeral honours in the church-yard of the Grey-friars in Edinburgh. As a statesman, the character of sir George Mackenzie stands high for learning and talents, and he was much esteemed for public and private worth. People of different parties and feelings will judge differently of his political exertions, but his integrity and good intentions seem unquestionable. In the midst of all his public business he found leisure to compose several literary pieces, among which are "Aretino, or a Serious Romance;" "Religio Stoici;" "A moral Essay on Solitude;" "Moral Gallantry," and a play and poems. These pieces gave him the reputation of an elegant writer and sound moralist. As a lawyer, he published "A Discourse upon the Laws and Customs of Scotland, in Matters criminal;" "Idea Eloquentiæ forensis hodiernæ, una cum Actione forensi ex unaquaque Juris Parte;" "The Institutions of the Laws of Scotland;" and "Observations upon the Acts of Parliament." As an advocate for monarchy, he wrote "Jus Regium," or the just and solid foundation of monarchy in general, and more especially of the monarchy of Scotland, and several other pieces. As an antiquarian and national historian, he wrote "Observations on the Laws and Customs of Nations as to Precedency, with the Science of Heraldry, as Part of the Law of Nations; and a Defence of the Royal Line and Antiquities of Scotland;" the latter treatise involved him in a controversy with Dr. Lloyd, bishop of St. Asaph, and Dr. Stillingfleet. He wrote a work likewise respecting an union between England and Scotland, entitled "Reflections upon the Advantages and Disadvantages that would happen by an incorporating Union between the two Kingdoms." Besides these, several additional moral and miscellaneous treatises issued from his pen, which demonstrated the fertility and variety of his speculations; and his aptness as a writer on almost all topics. He was the founder of the advocates' library in Edinburgh.

MACKENZIE'S *River*, in *Geography*, on the N.W. part of America, rises in Slave lake, runs a N.N.W. course, and after receiving a number of large rivers, discharges itself into the N. sea at Whale island, in N. lat. 69° 14', and between 130° and 135° W. long., its course from Slave lake having been 780 miles. It derived its name from Mr. Mackenzie, who ascended this river in the summer of 1789. The Indian natives inhabiting the W. side of the river from the Slave lake are the Strong-bow, Mountain, and Hare Indians; those on the E. side the Beaver, Inland, Nathana, and Quarrelers.

MACKERMORE, a small island near the W. coast of Scotland; about five miles E. from the island of Jura. N. lat. 55° 57'. W. long. 6° 43'.

MACKERTER'S HEAD, a cape on the E. coast of the island of Ilay. N. lat. 55° 52'. W. long. 5° 59'.

MACKÉY, JOHN, in *Biography*, an Englishman, who followed James II. to France after the revolution, and was admitted by that unfortunate monarch to his confidence, which he scandalously betrayed, by giving information to king William of every secret with which he was entrusted. As an author he is known by his "Picture of the Court of St. Germain," which was published in 1691; and his "Memoirs of the Court of England, in the Reigns of William and Anne," published at the Hague in 1733; this work abounds in curious anecdotes. He died in 1726 at Rotterdam.

MACKNIGHT, JAMES, a learned clergyman of the church of Scotland, was born at Irvine, in Ayrshire, in the year 1721. Having laid a good foundation in grammatical learning, he was at the age of fourteen sent to the university of Glasgow, where he displayed a most ardent thirst for knowledge, and secured to himself the approbation of his tutors. After he had completed the usual course of his studies at the Scotch college, he crossed the sea to Holland, and attended the lectures at the university of Leyden. His favourite study was theology, and on his return to Scotland he was licensed as a preacher by the presbytery of Irvine, and chosen to officiate at the Gorbals, near Glasgow. From thence he removed to Kilwinning, on the invitation of Mr. Ferguson, then minister of that place, and acted for some time as assistant in the duties of the parish. Here he established a character as a judicious and useful minister, and upon a vacancy taking place at Maybole, he obtained that living. He was ordained pastor in the month of May 1753, and continued to discharge the duties of that office full sixteen years. During this period, and amidst his various professional occupations, he composed his "Harmony of the Gospels," and his "New Translation of the Apostolical Epistles." Although the plan of the "Harmony" differed considerably from that of former harmonies, in supposing that the Evangelists have not neglected the order of time in the narration of events, the reception which it met with from the most competent judges was so favourable, that the author undertook a second edition in 1763, with improvements, and considerable additions, which consisted chiefly of six discourses on Jewish antiquities. A third edition was called for in 1804, which was published in two volumes 8vo. In the year 1763, Mr. Macknight published another work of great merit, entitled "The Truth of the Gospel History," which was the fruit of his studies and researches during the intervals between the two editions of his "Harmony." Its great object was to illustrate and confirm the internal, the collateral, and the direct evidences of the gospel history. On account of these publications the degree of doctor of divinity was conferred upon him by the university of Edinburgh. In 1769 he was chosen moderator or president of the general assembly of the church of Scotland, and was in the same year translated to the living of Jedburgh, which he held three years, when he was elected minister of lady Yester's parish in Edinburgh: from this he was translated, in 1778, to the old church, in which he continued during the remainder of his life. Dr. Macknight now devoted his time and talents to the promotion of various useful institutions as well as to the exemplary performance of his pastoral duties. He took a lead in the management of many different charitable institutions, and particularly of the

fund established by act of parliament, for a provision to the widows and fatherless children of ministers in the church of Scotland. As an author, Dr. Macknight occupied a considerable portion of his time in the execution of his last and greatest work on the apostolical epistles. This was the result of an almost unremitting labour during thirty years: he is said to have studied eleven hours in each day, and that before the work was sent to the press, the whole MS. had been written five times with his own hand. A specimen was published in 1787, being his version of the epistles to the Thessalonians: this was so well received, that in 1795 the whole was given to the public in four large volumes in quarto, under the title of "A new literal Translation from the original Greek of all the Apostolical Epistles; with a Commentary, and Notes, philosophical, critical, explanatory, and practical." The whole is interspersed with essays on several important subjects, and to the fourth volume is added a life of the apostle Paul, which includes a capital compendium of the apostolical history. Having finished this great work, which he had been accustomed to regard as the grand object of his life, he was desirous of enjoying the remainder of his days free from laborious pursuits, and refused, though earnestly solicited, to undertake a similar work with regard to the acts of the apostles. He probably felt the powers of his mind failing him, and had prudence and wisdom to obey the voice of reason and nature; and in a very short time after the decline of his faculties became manifest to his family. Towards the close of the year 1799 he caught a violent cold, which was the fore-runner of other complaints that put an end to his life in January 1800. "Dr. Macknight," says his biographer, "had acquired an early taste for classical literature, and studied the writers of antiquity with much critical skill. He was deeply read in metaphysical, moral, and mathematical science. His piety was sincere, rational, and without ostentation, and to be useful in the cause of truth and virtue was his highest ambition. In that branch of the pastoral office, which in Scotland is called lecturing, and consists in a familiar exposition of the sacred writings, his learning and ability were much admired, and never failed to please as well as to instruct and edify in a degree which has seldom been equalled. As a preacher, without pretensions to the graces of elocution, he had a certain earnestness of manner, evidently proceeding from the heart, and from a sincere anxiety to be useful, which always commanded the attention, and excited the interest of the hearers." See the *Harmony of the four Gospels*, third edition.

MACKREDIPET, in *Geography*, a town of Hindoostan, in Golconda; 30 miles S. of Indelavoy.

MACKREL, **SCOMBER**, in *Ichthyology*. See **SCOMBER**.

This fish was in high esteem among the Romans, because it furnished the precious garum. The best time of taking mackrel is during a fresh gale of wind, which is then called the mackrel gale. See *Mackrel Fishery*.

MACKREL, *Horse*. See **SCOMBER Trachurus**.

MACKUM, in *Geography*, a town of Holland, in the department of Friesland, on the Zuyder see; 25 miles W. of Bolfwaert.

MACLAURIN, **COLIN**, in *Biography*, descended of an ancient family, the possessors of the island of Tirrie, upon the coast of Argyleshire, was born at Kilmoddan, in the month of February 1698. His grandfather, Daniel, on leaving his island, removed to Inverara, and contributed very much to restore that town, after it had been almost entirely ruined in the time of the civil wars. John, the son of Daniel, and father to the subject of this article, was minister

of Glenderule; where he was greatly distinguished as a faithful and diligent pastor: he was employed by the synod of his province in completing the version of the psalms into Irish, which is still used in those parts of the country in which divine service is performed in that language. This gentleman, whose character was highly exemplary, died within six weeks of the birth of his son Colin, the care of whom devolved in a good measure upon an uncle, Daniel, who was minister of Kilfinnan. He was ably assisted in the charge by Mrs. Maclaurin during her life, which was extended only to the year 1707, when she died, leaving the care of all her children to the management and superintendance of an uncle. In 1709 Colin, though only eleven years of age, was sent to the university of Glasgow, where he continued five years applying himself with the utmost diligence to his studies. As he was a lad of considerable abilities, it need not be added that his success was fully proportioned to his exertions. He was accustomed to keep a diary, in which he inserted an account of almost every hour in the day; of the commencement and progress of every particular study, enquiry, or investigation, and of his conversations with learned men. In Dr. Robert Simson, and several other distinguished scholars, the youth met with ardent friends, who seemed to vie with each other who should most encourage him in his pursuits by opening to him their libraries, and admitting him into their society and most intimate friendship. The genius of this young man for mathematical learning discovered itself very accidentally, when he was only twelve years of age. He met with a copy of the Elements of Euclid, and in a few days made himself master of the first six books without any assistance, and thence following the natural bent of his inclination, he made such a surprising progress, that very soon after he engaged in the most curious and difficult problems. In his fifteenth year he took his degree of master of arts with much applause, on which occasion he composed and publicly defended a Thesis on the power of gravity. He now turned his attention to theology, and having spent a year in the study he quitted the university, and lived in retirement with his uncle, till the autumn of 1717, when he presented himself a candidate for the professorship of mathematics in the Marischal college of Aberdeen, which he obtained; and was afterwards the happy means of reviving the taste for mathematical learning, and raising it higher than it had ever been in that university. During the vacations of 1719 and 1721, he went to London, and was, in his first journey, introduced to Dr. Hoadly, Dr. Clarke, the illustrious Newton, and several other eminent men, whose notice and friendship he ever after reckoned the greatest honour and happiness of his life. In his first journey he was admitted a member of the Royal Society: two of his papers were inserted in their Transactions, and his book, entitled "Geometria Organica," was published with the approbation of their president. In 1721 he became acquainted with Martin Folkes, esq. afterwards president of the Royal Society, with whom he cultivated a most entire and unreserved friendship, frequently interchanging letters with him, and communicating all his views and improvements in the sciences. In the following year lord Polwarth, plenipotentiary of the king of Great Britain at the congress of Cambray, engaged Mr. Maclaurin to become travelling tutor and companion to his eldest son, who was then set out on his travels. After visiting Paris and some other cities and towns of France, they fixed on Lorraine as the place of their residence, where Mr. Maclaurin gained the esteem of the principal persons of the court. Here he wrote his piece on the percussion of bodies, which gained the prize of the Royal Academy of Sciences for 1724. The substance

substance of this tract was afterwards inserted in his treatise of Fluxions, and is likewise to be found in the second book of his "Account of the Discoveries of Newton." Shortly after they quitted Lorrain, Mr. Maclaurin's pupil was seized with a fever which terminated fatally, to the great grief of the preceptor, who mourned for him as for a companion and the friend of his heart. He immediately returned to Aberdeen; and was in a short time, by the recommendation and interest of sir Isaac Newton, chosen assistant to Mr. James Gregory in the professorship of mathematics at Edinburgh. He soon became a very popular lecturer, and seldom had less than a hundred young persons attending his course. These, according to their standings in the university, he divided into classes: in the first he taught the first six books of Euclid's elements, plain trigonometry, practical geometry, the elements of fortification, and an introduction to algebra. With the second class he entered more largely into algebra, read the 11th and 12th books of Euclid; and instructed them in spherical trigonometry, conic sections, and the general principles of electricity. The third advanced in astronomy and perspective, and read a part of sir Isaac Newton's Principia, and had a course of experiments for illustrating them performed and explained to them. He afterwards read and demonstrated the elements of fluxions: with the next class he read a system of fluxions; and introduced the pupils to the doctrine of chances, and explained the remainder of Newton's Principia.

Besides the labours of his public profession, Mr. Maclaurin was engaged in many other important avocations. If a new or uncommon experiment was said to have been any where exhibited, the curious among Mr. Maclaurin's friends were desirous of having it repeated by him; or if a comet or eclipse was to be observed, his telescopes were always in readiness. Amidst all the hindrances which he almost perpetually was experiencing, he continued to pursue his studies with the utmost assiduity, and took from the ordinary hours of sleep, what he bestowed on his scholars and friends, a circumstance that is thought to have impaired his health and shortened his valuable life. In 1733, Mr. Maclaurin married Anne, the daughter of Mr. Walter Stewart, solicitor-general to king George I. for Scotland, by whom he had seven children; of these, five survived him. In 1734, Dr. Berkeley, bishop of Cloyne published his treatise entitled "The Analyst," in which he attempted to overturn the doctrine of "Fluxions," and to charge mathematicians with infidelity in matters of religion. This work was the occasion of Mr. Maclaurin's elaborate Treatise on Fluxions, which was published at Edinburgh in 1742, and which is reckoned the most complete treatise on that science that has even yet appeared. He became a very active and distinguished member of the society which had existed some years at Edinburgh for the improvement of medical knowledge, but which he contrived to extend more generally to the interests of science in all its branches. In conjunction with Dr. Plummer, professor of chemistry, he was appointed joint secretary, and generally at the monthly meetings either read some paper of his own, or communicated the contents of letters received from foreign parts, by which means the society was informed of all the new discoveries and improvements in the sciences. He shewed his zeal for promoting the interests of science, by projecting the building of an "Astronomical Observatory," and a theatre for experiments in the university, of which he drew an excellent plan, and would probably have carried it into execution by the munificence of private persons, had not the unhappy disorders of the country intervened. In the year 1739, he was consulted by the earl of Morton with regard to

the settling of the geography of the Orkney and Shetland islands, which had been laid down in the maps without attention to real facts deduced from astronomical observations. He drew up a memorial of what was necessary to be done, furnished the proper instruments, and recommended Mr. Short, the celebrated optician, as a fit person for managing the affair. From the account which he received of this visit to those islands, he was made more sensible than before of the errors in their geographical situation, which have proved the occasion of numerous shipwrecks, and he engaged several of his old pupils, who were then settled in the northern counties, to survey the coasts, expecting, as the result of their observations, to obtain a good map of Scotland. He had at this time another scheme for the improvement of geography and navigation, which was the discovery of a passage from Greenland to the South-sea by the north pole: he was satisfied that such a passage existed, and would, if his situation could have admitted of it, have undertaken the voyage at his own expence. A premium was afterwards offered by government for the discovery of a north-west passage, which did not accord with his views, as he was convinced, from all his reading on the subject, that it must lie near the pole. In the year 1745, he took a most active part in favour of his majesty's government, in opposition to the rebels who were marching to the south. By the fatigue and anxiety to which he was exposed by his exertions in this cause, he laid the foundation of the disease which in a few months put a period to his life. When, however, the rebel army got possession of the city, he thought it advisable to make his escape into England, well knowing that he could not expect mercy if he fell into the hands of the enemy. As soon as he arrived in the neighbourhood of York, he was invited by the archbishop to reside with him during his stay, with which he gladly complied, and on account of which he was impressed with the deepest sentiments of gratitude. Upon the march of the rebels into England, he ventured to return to Edinburgh, when it was found his constitution was completely undermined: and that his disorder had already advanced beyond the reach of medicine. His complaint being the dropsy, he was three times tapped, but the operations proved inefficacious, and he died on the 14th of June 1746, having exhibited, through the progress of his disease, a disposition worthy of a philosopher and a Christian.

Mr. Maclaurin was not only distinguished by his genius and learning, but by the qualities of the heart: by his sincere love to God and his fellow creatures, and by his universal benevolence and unaffected piety. His favourite studies were the mathematics, which he cultivated with extraordinary success. His peculiar merit as a philosopher was, that all his studies were accommodated to general utility, and in many parts of his works, there is evidently an application of his most abstruse theories to the perfecting of mechanical arts. He had resolved, for the same purpose, to compose a course of practical mathematics, and to rescue several useful branches of the science from the treatment which they too frequently meet with in less skilful hands. These designs were prevented by his death: in his life-time, however, he frequently had the pleasure to serve his friends and country by his superior attainments. If any difficulty occurred concerning the construction or perfecting of machines, the working of mines, the improvement of manufactures, &c. Mr. Maclaurin was ever ready to resolve them. He was likewise employed to terminate some disputes which had arisen at Glasgow concerning the gauging of vessels; and presented to the commissioners of excise two elaborate memorials, containing rules by which the officers acted, with

with their demonstrations. He made calculations relative to the fund for the widows of the Scotch clergy, and of the professors in the universities, and contributed very much to perfect the scheme which has been found of eminent utility to a vast number of persons who would otherwise have been left destitute of the means of support. But what seems to have endeared his studies to him, was the use they are of in demonstrating the existence and attributes of the Creator, and establishing the principles of natural religion on a solid foundation. To this use Mr. Maclaurin frequently applied them: and he was equally zealous in the defence of revealed religion, which he would warmly vindicate, whenever he found it attacked either in conversation or writing. Besides the works already mentioned, Mr. Maclaurin was author of many papers in the Philosophical Transactions; "On the Construction and Measures of Curves;" "On Equations with impossible Roots;" "On the Description of Curves," &c. He gave an "Account of the Annular Eclipse of the Sun at Edinburgh in January 1742—3." After his death were published his "Treatise on Algebra," and his "Account of sir Isaac Newton's philosophical Discoveries." The first of these is a capital introduction to the science of which it treats. The author's design with regard to the second seems to have been to explain only those parts of sir Isaac's philosophy which have been, and which were, for some time, controverted, which was probably the reason that his discoveries concerning light and colours were scarcely touched on.

Such was the life of this eminent person, spent in a course of laborious study; in continually endeavouring to be useful; in improving curious and useful arts, and propagating truth, virtue, and religion amongst mankind. "He was," says his biographer, "taken from us at an age when he was capable of doing much more, but has left an example, which will be long admired and imitated, till the revolution of human affairs puts an end to learning in these parts of the world; or the fickleness of men, and their satiety of the best things, have substituted for this philosophy some empty form of false science, and by the one or the other means, we are brought back to our original state of barbarity." Account of the Life, &c. of the Author prefixed to the work last-mentioned.

MACLAURIN, JOHN, Lord DREGHORN, son of the above, born at Edinburgh in December, 1734, was educated at the grammar-school of Edinburgh, and afterwards went through an academical course at the university of that city. He was admitted a member of the faculty of advocates at Edinburgh in 1756. In 1782, a Royal Society was established in Edinburgh, of which Mr. Maclaurin was one of the original constituent members, and at an early period of the institution he read an Essay to prove that Troy was not taken by the Greeks. In 1787 he was raised from the Scottish bar, at which he had practised long and successfully, to the bench, by the title of lord Dreghorn. He died in 1796. As an author we have "An Essay on Literary Property;" "A Collection of Criminal Cases;" "An Essay on Patronage;" and some poetical pieces: besides which we have in the dramatic line ascribed to him, "Hampden;" "The Public;" and "The Philosopher's Opera." During the years 1792, 3, 4, and 5, lord Dreghorn kept a journal, or diary, in which he recorded the various events that happened in Europe during those years. From this journal he made a selection for publication: and in 1799 a selection of his lordship's works was printed in two vols. 8vo. Biog. Dram.

MACLE, in *Mineralogy*. *Macle basaltique, ou schorl en pri m' quadrangulaires rhomboïdaux*, Romé de l'Isle; *Chiasfolit'*, Karsten; *Hohlspar*, Werner; *Hollow-spar*, Jame-

son; *Crucite*, Delameth; *Argilla chiasfolitibus*, Lat. (not of Forster.)

This remarkable mineral has hitherto been found only crystallized; but its forms are very different from those of all other mineral substances we are acquainted with, and not easily determinable.

It is generally found in long, slightly rhomboidal prisms of a yellowish, reddish or greenish colour; each prism is apparently produced by four tabular or prismatic crystals, externally straight and more or less exactly joined, internally more or less separated from one another: the space thus left in the centre of the prism, and varying both in form and extent, is filled up with a black or blueish-black substance; whence a transverse section of the complete prismatic crystal represents a black nucleus, generally of a slightly rhombic figure, from each angle of which a black line runs towards the opposite angle of the external substance, producing a kind of cross, more or less dilated in the centre, (*Macle tétragramme* of Haüy, pl. 51. f. 219.) and generally equally dilated at its four extremities (*Macle pentakombique*, Haüy, ib. fig. 220.) Sometimes the same black diagonal lines branch out into other lines, (*Macle polygramme*, Haüy, ib. fig. 221.) In the narrow prismatic variety the black substance forms by far the principal part, appearing in the form of a prism, enclosed in a thin case of the same form, and of a yellowish-white colour.

The black rhombic figure in the centre of the horizontal section of the crystals appears at first sight to belong to a prism; but it is generally the section of a pyramid, as is manifested by the increasing or diminishing size of the rhombic spot, according as the transversal sections are made nearer to one or to the other extremity of the crystal.

The crystals are generally middle-sized, sometimes very narrow and acicular; they sometimes adopt a cylindrical form.

Fracture more or less foliated, with a double cleavage; the principal one parallel to the lateral planes of the prism.

It is translucent on the edges, at least in those crystals that have the appearance of felspar; those that approach to the nature of teatite are opaque.

Hardness variable, according as the substance exhibits the appearances just mentioned.

Specific gravity 2.9444, Haüy; 2.927, Karsten.

Before the blowpipe it is converted into a whitish scoria; the internal black substance melts into a blackish glass.

This substance has not been subjected to chemical analysis.

Macle occurs imbedded in clay-slate. Mr. Buch suspects that the streaked and spotted appearance of some of the varieties of primitive clay-slate, called *frucht* or *kukuk-schiefer*, is produced, not by hornblende, but by minute crystals of macle or hollow spar.

It is found at Gefrees, in the margraviate of Bayreuth; in ci-devant Brittany, in France; and near St. Jago di Compostella, in Galicia. Those of Brittany are more exactly quadrangular. Some of them have about four and a half lines in diameter, and upwards of three and a half inches in length. Those of Spain are generally much thicker, and of a rounded form. According to Haüy, the external surface both of the Spanish and French macles frequently exhibits something of a pearly lustre.

It has also been observed by Lelièvre and Dolomieu in the valley of Baréges, in the Pyrenees; and by Raimond on the plateau de Troumouze, in the High Pyrenees. This substance has also been found by Mr. Davy in the clay-slate of Cumberland, and in the county of Wicklow in Ireland, where it has likewise been observed by Dr. Fitton. Pro-

feffor Link has found it in the mica slate of the Serra de Marao in Portugal.

The macle has been mentioned by Boëtius de Boot under the name of *lapis cruciger*. It was applied at his time as an amulet for stopping hemorrhages, &c.; and even at the present day it is used for several superstitious purposes.

Werner considers this substance as nearly related to felspar. Dr. Fitton and Mr. Stephens, in their very interesting "Notes on the Mineralogy of Part of the Vicinity of Dublin," suspect that a connection exists between the macle and the andalusite (*Feldspar apyre* of Häuy); the former gentleman, in particular, has convinced himself that colour, fracture, lustre, and other characters observable in the crystalline part of the former substance, completely agree with those of the andalusite.

MACLE, *Cristaux maclés*, *Macleed crystals*, are the names by which several mineralogists, and principally Romé de l'Isle, have distinguished the crystals with re-entering angles, formed by the union of two distinct crystals, producing the appearance of two halves of one symmetrical crystal, which in the act of uniting have turned on each other in such a manner, that the planes of the upper part of the one correspond to those of the lower part of the other, or nearly so. Such crystals are denominated *cristaux transposés* and *hémitropes* by Häuy; and *Zwillings-krystalle* by Werner.

MACLIN, CHARLES, in *Biography*, a native of Ireland, probably born in the county of West Meath, of a family named M'Laughlin, which was anglicised to that by which he was ever afterwards known. He was born about the 1st of May 1690, and in 1708 absconding from his mother, then a widow, he came over to England. For some misconduct with regard to a female connection he was sent back to Ireland. Here he formed an acquaintance with certain undergraduates of Trinity college, Dublin, and took up the employment of bargeman in that college, read much for the improvement of his mind, and remained in that degraded state till he had attained the age of twenty-one. He then came to London, made a connection with a strolling company of players, and acted the part of harlequin. After leading an extraordinary course of life, he was again restored to his mother, and returned a penitent to his former station in Trinity college. In 1716 he arrived in England for the third time, joined a company of players at Bristol, then attached himself to several strolling companies, and afterwards made his entrè at the theatre in Lincoln's-inn-Fields, where his merit was first discovered in a trifling character in Fielding's "Coffee-house Politician," which, it is said, would in any other hands have gone unnoticed. He now for several successive seasons performed comic characters, and on the tenth of May 1735, had the misfortune to kill Mr. Hallam, an actor in the same theatre with himself, in a private quarrel. He was brought to trial in consequence; but no malicious intent appearing in evidence he was acquitted. In 1741 he established his fame as an actor, in the character of Shylock in "The Merchant of Venice," and by his fine and impressive manner restored to the stage a play which had been forty years supplanted by lord Lansdown's "Jew of Venice." The manager and performers having about this time disagreed, Maclin, and several of the most eminent of the company, among whom was Garrick, revolted, and signed a formal agreement, by which they were bound not to accede to any terms which might be proposed to them by the patentee, without consent of the subscribers. The seceders applied, but without effect, for the grant of a new patent, of course they found themselves under the hard necessity of agreeing to the terms offered by the manager, who ascribed the revolt of the players to the influence and

suggestion of Maclin, and resolved to punish him for his ingratitude. To the others he was reconciled, but the sentence of eternal banishment from his theatre was pronounced against the man who had been once his friend and adviser. A change in the management, by which Mr. James Lacey succeeded Fleetwood, restored Maclin to his usual employment. This was in 1747, and in the following spring he accepted an invitation from the manager of the Dublin theatre, by which he engaged his services for two years, but scarcely had he gone through the duties of his station a single month, when he took offence at some instances of supposed neglect, which ended in a separation from that concern. After various incidents, he, in 1753, obtained from Mr. Garrick the use of his theatre for a single night, and took a formal leave of the stage, in a prologue written for the occasion, in which he introduced his daughter as an actress to the protection of the public. He now projected the establishment of a tavern and coffee-house which was to make his fortune: this he soon after converted into a debating and spouting club, under the name of "The British Inquisition:" but Maclin was wholly unfit for the business of a tavern-keeper, became a prey to every needy and unprincipled villain, and, in Feb. 1755, was seen in the list of bankrupts. On his examination before the commissioners every thing turned to his character, except that he had been miserably deficient in prudence, and in the end he paid twenty-shillings in the pound. He next joined Mr. Barry in founding a new theatre in Dublin, where, however, he did not remain more than two or three years, and in 1759 he returned to London and made an engagement at Drury-lane, at a very considerable salary, and brought out his farce of *Love a-la-Mode*, which, though opposed at first, was received in London and at Dublin with unbounded applause. Maclin in a short time transferred himself from Drury-lane to Covent Garden theatre, to which he continued uniformly attached. He obtained great and almost universal and unbounded applause as an actor in comedy, but in 1773 he was determined to attempt the character of Macbeth in tragedy; in this new line he gave full satisfaction to his friends; but the public, headed by a few violent spirits, probably his personal enemies, were so much enraged at his attempting tragedy, that for a long time they would not admit him in his own comic parts, and he was formally dismissed from the theatre. In 1775 he brought his action against his opponents, and having obtained a verdict in his favour, he willingly relinquished the damages awarded in his favour upon the most liberal terms, a circumstance which drew from lord chief justice Mansfield the following handsome and well-turned compliment; "You have met with great applause to-day: you never acted your part better." From this period Maclin occasionally performed and paid a visit to Dublin during Mr. Daly's management. In 1788, and again in 1789, while acting his favourite characters, he suddenly lost his memory, and in the second instance he resolved to make no other effort; but by the advice of his friends he published by subscription his two pieces "The Man of the World;" and "Love a-la-Mode:" by the exertions of Mr. Murphy, who superintended the printing, and his other friends, 1500*l.* was raised, with which an annuity of 200*l.* was settled on himself, and 75*l.* per ann. on his wife, if she survived him.

Mr. Maclin died on the 11th of July 1797, at the age of 107, if he were born at the period before-mentioned, but of this the reader should be apprized there were some serious doubts entertained. His remains were interred under the chancel of Covent Garden church. Mr. Maclin, says his biographer, was in his private character a tender husband, a good father, and a steady friend. To his firmness and reso-

lution in supporting the rights of his theatrical brethren, it was owing that they have been relieved from a species of oppression to which they had been ignominiously subjected for many years, whenever the caprice or malice of their enemies chose to exert itself. We allude to the prosecution which he carried on against a set of insignificant beings, who, calling themselves "The Town," used frequently to disturb the entertainments of the theatre, to the terror of the actors, as well as to the annoyance and disgrace of the public. As a comedian his principal and most important parts were sir Gilbert Wrangle in "The Refusal;" sir Archy M'Sarcasm in his own farce of "Love a-la-Mode;" and sir Pertinax Mac Sycophant in "The Man of the World," written also by himself, and first brought forward in 1781. Maclin also made a fine figure in the character of Shakspeare's Iago; but the part in which he was allowed to shine without a competitor was that of Shylock. Besides the dramatic works already referred to, Maclin wrote a tragedy of "King Henry VII. or the Popish Impostor;" "A Will or no Will;" "The suspicious Husband criticised; or the Plague of Envy;" "The Fortune Hunters;" and some other pieces. Biog. Dram.

MACNEN-ABAD, in *Geography*, a town of Persia, in Segestan; 111 miles S.S.E. of Zareng.

MACOGUA, a fort on the W. coast of Africa, at the mouth of the St. Domingo river. N. lat. $12^{\circ} 20'$.

MACOKETH, or **MACOKETCH**, *Great*, a river of America, which runs into the Mississippi from the north-west, in N. lat. $42^{\circ} 23'$. *Little Macoketch* falls through the E. bank of the Mississippi about 45 miles above the mouth of the former.

MACOLOE, one of the Querimba islands, in the Indian sea. S. lat. $11^{\circ} 10'$.

MACOMER, a town of the island of Sardinia; 16 miles W. of Bosa.

MACON, a town of France, principal place of a district, and capital of the department of the Saône and Loire, near the Saône; before the revolution the metropolis of a small country called the "Mâconnois," which was formerly a county and the see of a bishop. It contained four churches, a commandery of Malta, seven convents, a college, and an hospital. Its trade is considerable. The place contains in two cantons 5807, and the cantons 20,252 inhabitants, on a territory of $177\frac{1}{2}$ kilometres, in 28 communes. N. lat. $46^{\circ} 18'$. E. long. $4^{\circ} 55'$.

MACONDEGAY ISLANDS, three small islands in the bay of Gunong-Tellu, on the E. coast of the island of Celebes. S. lat. $0^{\circ} 30'$. E. long. $120^{\circ} 25'$.

MACONIA, a town of Pegu; 20 miles S. of Pegu.

MACOPIN, a small river of America, which runs from the S.E. into the Illinois, 18 miles from the Mississippi, 20 yards wide and navigable nine miles in the hills; the shore, which is low, is covered with maple, ash, button-wood, &c.: the land abounds with timber, and is overrun with high weeds.

MACORIZ, a small river on the S. side of the island of St. Domingo; 16 leagues E. of the city of St. Domingo.

MACOTERA, a town of Spain, in the province of Leon; 18 miles E. of Salamanca.

MACOTTO, a town on the S. coast of the island of Luçon. N. lat. $13^{\circ} 12'$. E. long. $123^{\circ} 8'$.

MACOU, a town of Persian Armenia; 75 miles S. of Erivan.

MACOUBA ST. ANN, LE, a town of the island of Martinico. N. lat. $14^{\circ} 54'$. W. long. $61^{\circ} 17'$.

MACOUBEA, in *Botany*, occurs only in Jussieu and Aublet, the former having taken it from the Supplement of

the latter author's work on the Plants of Guiana, where it is figured in t. 378.—The only parts of fructification with which they were acquainted, are *Peric.* Capsule orbicular, slightly compressed, sometimes obtusely triangular, of one cell; hollow within; rough, reddish and marked with grey spots on the outside. *Seeds* numerous, oblong, incurved, obtuse, convex above, furrowed below, enclosed in a white membrane, and attached to the internal coat of the pericarp.—*M. guianensis* is a tree rising to the height of forty feet. Its *wood* is of a greenish-yellow, and in drying has a disagreeable smell. *Leaves* opposite, on footstalks, ovate, acute, entire. *Fruit* as big as oranges, in clusters, at the divarications of the branches. The whole tree abounds with a milky juice.—Aublet found it in the woods of Guiana, bearing fruit in February. Jussieu places *Macouba* in the natural order of *Guttifera* on the authority of Aublet's description.

MACOUCOUA, is the Caribbean name of the plant in question, as we learn from Aublet.—It is noticed by Jussieu as nearly allied to *Ilex*, but figured by Lamarck under its vernacular and generic name.—Aubl. Guian. 88. Lamarck Dict. v. 3, 669. Illustr. t. 75. Juss. 379.—Class and order, *Tetrandria Monogynia*. Nat. Ord. *Rhamnif.* Juss.

Gen. Ch. *Cal.* Perianth inferior, of one leaf, cloven into four, short, acute segments. *Cor.* of one petal, tubular, standing upon the receptacle; tube very short; limb divided into four, roundish lobes. *Stam.* Filaments four, within the divisions of the corolla; anthers roundish, of two cells. *Pistl.* Germen superior, very small, roundish; style none; stigma obtuse. *Peric.* and *Seeds* unknown.

1. *M. guianensis*. Aubl. Guian. t. 34. Lamarck Illustr. t. 75. The only species known. A native of woods in Guiana and Cayenne, flowering in February.—The *trunk* of this tree is thirty or forty feet in height, much branched. *Bark* thick, hard, brittle, white externally. *Leaves* alternate, nearly sessile, polished, oval, obtuse and sometimes ending in a sort of jagged point. *Flowers* corymbose, axillary, on footstalks, white. *Fruit* unknown.—The natives use the bark of this tree merely for fuel.

MACOURIA, in *Geography*, a river of Guiana, which runs into the Atlantic, N. lat. 5° . W. long. $53^{\circ} 46'$.

MACOWAL, a town of Hindoostan, in the circar of Sirhind; 50 miles N. of Sirhind.

MACOYAQUI, a town of New Mexico, in the province of Mayo; 70 miles E.N.E. of Santa Cruz.

MACPHERSON, JAMES, in *Biography*, a modern writer of some celebrity, was born, in 1738, at Ruthven, in the county of Inverness. He studied at the universities of Aberdeen and Edinburgh, and while he was a resident at the latter, he published a poem, entitled "The Highlands," which displayed some genius, though undisciplined by good taste. He was intended for the church, but never entered upon its duties. In 1760 he was living as private tutor in the family of Mr. Graham, of Balgowan, and about this time he published "Fragments of Ancient Poetry, collected in the Highlands of Scotland, and translated from the Gaelic and Erse Languages." The singularity of these pieces, and the novelty of their style and imagery, and the idea that they were the product of a remote age and rude people, caused them to be received with great interest by many lovers of poetry; and as hopes were given that other works of the same kind might be recovered, a subscription was set on foot to enable Macpherson to leave his employment, and visit the Highlands for that purpose. The result of this mission, or of his own leisure, was the epic poem of "Fingal," and several other pieces, which were said to be composed

composed by Ossian, the son of Fingal, king of the Highlands. An animated controversy was soon kindled relative to their authenticity: the Scotch were, in general, on the side favourable to the national honour; but many learned and able writers in the southern part of the island rejected their claims to the antiquity assumed. The arguments urged against their authenticity, were drawn from the improbability of the existence and preservation of regular epic poems among an uncivilized people who had not the use of letters; the abundance of poetic ornament, and the elevation and delicacy of moral sentiment, together with the freedom from all mixture of puerility and extravagance. Whatever was their origin, they met with a number of enthusiastic admirers, and were translated into several languages: they were commented upon by critics, and admitted as evidence of manners, habits, and customs by historians and antiquarians. The blind Ossian was placed in company with the blind Homer, and the wild mountains and heaths of the Highlands were converted into classic ground. The originals were now loudly called for, and indirect promises made that they should appear, till at length the supposed translator, instead of convincing or conciliating the sceptical, attempted to silence them by a tone of insolent assumption. The controversy, however, continued during the life of Macpherson, and is not, indeed, at this moment completely terminated, there being still advocates who justify the claims of Ossian as the real author of the works published under his name. Dr. Aikin, in the *General Biography*, observes, that the late masterly discussion of the topic by Mr. Laing seems to have produced a general opinion, that at least the great mass of the poems is modern fiction; and curiosity is now mostly limited to the enquiry how far it may have had a foundation in the traditional stories still current in the Highlands. In 1764, Mr. Macpherson was taken by governor Johnstone to Pensacola, in Florida, as his secretary. After executing his office in settling the government of that colony, he visited several of the West India islands, and some of the North American provinces, and returned in 1766. Resuming his literary pursuits, he published, in 1771, "An Introduction to the History of Great Britain and Ireland," which is elegantly written, and contains much valuable matter. He next published a sort of prose translation of Homer, which obtained for him neither fame nor profit, and was soon dismissed to total oblivion. He now devoted himself wholly to historical and political composition, and in 1775 published "The History of Great Britain from the Restoration to the Accession of the House of Hanover," in two volumes, quarto. This was at the same time accompanied with two other volumes of original papers, serving as documents and authorities for the history. Although the author discovered a considerable predilection for the Stuart family, and appeared to place too much confidence in the representations of facts made by James II. in the manuscript memoirs of his own life, yet it certainly made a valuable addition to the knowledge of that period of English history. Mr. Macpherson next engaged in political warfare, and when the resistance of the Americans called forth the pen, as well as the sword of authority, he was engaged as one of the ablest. He published a pamphlet, entitled "The Rights of Great Britain asserted against the Claims of the Colonies," for which he obtained great credit, on account of the style and argument: it was very industriously circulated by the agents and adherents of government. This was printed in 1776, and in 1779 he wrote "A Short History of the Opposition during the last Session of Parliament," which was highly commended. His services were not neglected, and he received from those, whose cause he

vindicated, the lucrative post of agent to the nabob of Arcot, whose concerns with the East India company were, at that period, very perplexed. Mr. Macpherson did not receive the emoluments without performing the duties of his office, and wrote several appeals to the public in behalf of this potentate; and it being judged necessary that the nabob should have a representative in the house of commons, he was returned, in 1780, to serve in parliament for the borough of Camelford, and was re-elected in 1784 and 1790. After this we find that his health was in a declining state, he retired to a seat which he had built, called Bellevue, near Inverness, where he died, in February 1796. His remains were deposited in Westminster Abbey: he bequeathed 300*l.* to be laid out in a monument of him, to be erected at Bellevue; and 1000*l.* to defray the expence of printing and publishing the original Ossian. *Gen. Biog.*

MACPHERSON'S *Strait*, in *Geography*, a channel in the Mergui Archipelago, between Banks's island and St. Sulfanna. N. lat. 10° 37'.

MACQUER, JOSEPH, in *Biography*, a physician and eminent chemist, was born at Paris in 1710, and became a doctor of the faculty of medicine in the university of that metropolis, professor of pharmacy, and censor-royal. He was, likewise, a member of the Academies of Sciences of Turin, Stockholm, and Paris, and conducted the medical and chemical departments of the *Journal des Sçavans*. He had the merit of pursuing chemistry, not so much with a view of multiplying the preparations of pharmacy, which had constituted the leading enquiries of experimentalists before his time; but engaged in it as a department of natural philosophy, and gained a considerable reputation by the publication of several useful and popular works on the subject. In fact, he was one of the most successful cultivators of the science, upon rational principles, previous to the new modelling which it has received within the last twenty-five years. He died in 1784. The following is a list of his publications: 1. "Elemens de Chymie Theorique," 1749—1753, 12mo. 2. "Elemens de Chymie Pratique," two volumes, 12mo. 3. "Plan d'un Cours de Chymie experimentale et raisonnée," 12mo., 1757. This was composed in conjunction with Mr. Baume, who was associated with him in his lectures. 4. "Dictionnaire de Chymie," two volumes, 8vo., 1766. These works have all been translated into English and German; the Dictionary particularly by Mr. Keir, with great additions and improvements. 5. "Formulæ Medicamentorum Magistralium," 1763; and he had also a share in the composition of the "Pharmacopœia Parisiensis," of 1758. *Eloy Dict. Hist. de la Méd. Gen. Biog.*

MACQUER, PHILIP, an historical writer, was born at Paris in 1720. He was brought up to the bar, but the weakness of his constitution prevented him from taking an active part in his profession, and he accordingly devoted himself to literary occupations. His principal works were "Abregé Chronologique de l'Histoire Ecclesiastique," three volumes, 8vo., composed after the manner of Hesnault's Chronological History of France; "Les Annales Romains;" and "Abregé Chronologique de l'Histoire d'Espagne et de Portugal," two volumes, 8vo. He had a share in the "Dictionnaire des Arts et Metiers," and other considerable works. He died in 1770, leaving behind him an excellent character for simplicity and unaffected integrity.

MACRÉUSE, in *Ornithology*, the *Anas Nigra*, Scoter or Black Diver. See DUCK.

MACRI, or MACARI, in *Geography*, a town of Asiatic Turkey, in Natolia, in a bay of the Mediterranean, called the gulf of Macri, anciently "Glaucus Sinus;" 70 miles S.W. of Satalia. N. lat. 36° 58'. E. long. 29° 30'.

MACRIANUS, TITUS FULVIUS JULIUS, in *Biography*, an Egyptian of obscure birth, who, from a private soldier, rose to the highest command in the army, and proclaimed himself emperor when Valerian had been made prisoner by the Persians, A.D. 260. He maintained his usurped power by the influence of his liberality: his two sons, Macrianus and Quietus, were invested with the imperial purple, and during a short period the enemies of Rome were severally defeated either by the emperors or their generals. When he had supported his dignity for a year in the Eastern parts of the world, Macrianus marched towards Rome to crush Gallienus, who had been proclaimed emperor. He was defeated in Illyricum by the lieutenant of Gallienus, and put to death, with his son, at his own desire.

MACRINUS OPILIUS, a native of Cæsarea, in Africa, who from the lowest origin rose to the high dignity of emperor of the world. He is said to have been a slave, and to have exhibited in public shows in the character of a gladiator, which facts have been doubted, as he raised himself to reputation as a pleader in the courts. He became the steward of Plautianus, the minister of Severus, and on his disgrace and fall he narrowly escaped with his life, and was banished to Africa, where he maintained himself by the united professions of rhetorician, pleader, and counsellor. After some absence he was recalled from his exile by Severus, who made him post-master on the Flaminian way. Caracalla afterwards created him a Roman knight, and he rose through the different employments to the high office of pretorian-prefect, an office which he filled with honour and integrity. He at length became an object of the emperor's suspicions, and saw, or imagined that he saw, his own safety entirely depended upon striking the first blow, and accordingly engaged a discontented soldier to stab the tyrant, which he effected. He immediately succeeded to the vacant throne by an election of the soldiers in the year 217, and the senate confirmed the choice of the military. Macrinus was not destitute of qualities and principles worthy of his high station, and by the punishment of informers, and the respect which he himself paid, and which he caused others to pay to the laws, he restored tranquillity to his country. These promising appearances did not long continue, and the timidity which Macrinus betrayed in buying a peace of Artabanus, the Parthian, by a large sum of money, rendered him odious to his subjects, and while he affected to imitate the virtuous Aurelius, without possessing the good qualities of his heart, he became contemptible and insignificant. The army, who had raised Macrinus to the purple, now took a decided part against him; the whole army mutinied, and their tumult was increased by the consciousness of their power and numbers. At this time the young Basianus was produced as the natural son of Caracalla, and was declared emperor by the army. Macrinus, at first, was resolved to oppose his competitor: the two armies met, and a bloody battle ensued: the fortune of the day remained some time very dubious, when Macrinus, who might probably have been victorious had he been firm and steady, shamefully fled, leaving his enemies in possession of the field, and eventually of the crown. He passed through Antioch, crossed Lesser Asia in disguise, and arrived at Chalcedonia with the intention of passing over into Europe; but being there recognised, he was seized and conveyed towards Cappadocia. On the road news was brought him that his son had been taken prisoner and put to death, which so enraged him, that he leaped from the chariot, and in the fall broke his arm; the guards, dreading the loss of their captive, instantly dispatched him, and carried his head to his rival. This circumstance happened in the month of June 218, after a reign of fourteen months.

Historians mention, to the honour of this emperor, that he meditated a great reform in jurisprudence, by abolishing all those imperial rescripts which had obtained the authority of laws, though often issued on particular occasions, and dictated by the caprice of the prince on the throne; but the shortness of his reign prevented the execution of this and other plans which he had devised for the public good. Gibbon. *Crevier*.

MACRINUS, SALMONEUS, a modern Latin poet, whose proper name was John Salmon, was born at Loudun, and flourished in the sixteenth century. He obtained so high a reputation as a poet, especially in the class of Lyrics, that he was called the Horace of his time. He was appointed preceptor of the two sons of René, of Savoy, and acquitted himself so well in this employment, that he was received at court, and acquired the friendship of several of the principal persons who frequented it. He wrote a great number of verses, of which some of the best are those to his wife. He died in the year 1557. Several of his poems are contained in the second volume of the "*Deliciae Poetarum Gallicorum*:" and a collection of his select hymns was printed by R. Stephanus. He had a son Charles, who is said to have surpassed his father in his knowledge of the Greek language, and to have equalled him in his Latin poetry. He was appointed preceptor to Catharine of Navarre, sister of Henry IV., and unfortunately perished in the bloody massacre of St. Bartholomew. *Moreri*.

MACROBIUS, AURELIUS THEODOSIUS, a Latin writer and eminent critic, who flourished towards the close of the fourth century, is supposed to have been a Greek, but the place of his birth is unknown. He is, indeed, claimed by the people of Parma, who shew his tomb, but he refers his birth-place to a country in which the Latin language was not vernacular. He undoubtedly lived at Rome, but it is not known whether he was the same Macrobius who was great chamberlain under Honorius and Theodosius II. It has likewise been disputed whether he was with regard to his religion a Christian or Pagan. The supposition that he held the office of chamberlain under the Christian emperors has been the chief, or, perhaps, the only ground for imagining him to have been a Christian, since the language of his writings and the interlocutors in his dialogue are entirely heathen. He wrote a Commentary on Cicero's "*Dream of Scipio*," from which it appears he was a Platonist: and a dialogue, entitled "*Saturnalia*," or Miscellanies, which was supposed to have been written at a festival of Saturn, by a company of learned persons, whose names are those of some of the most learned scholars of that time. The questions treated of related to topics of antiquity, mythology, history, and poetry, discussed in a pleasing way, and with references to the works of ancient authors, and to the laws and customs of the Romans; and although the style is not pure, and the arrangement cannot be commended, yet it is a work of considerable merit, and of much utility as a help to classical erudition, and as containing some curious observations on the two greatest epic poems of antiquity. The best editions of this author are those of the Variorum; and Gronovius in 1670, and Leipzig in 1777. Macrobius has been regarded and censured as a plagiarist, but without just reason, as he expressly mentions, in his preface, an intention of borrowing from any existing authors whatever might suit his purpose.

Many of the works of Macrobius are still preserved, among others, his Commentary on Cicero's *Somnium Scipionis*, and his *Saturnalia*, in seven books. In this last work there are many interesting passages concerning ancient music.

MACROCEPHALUS, in *Natural History*, a genus of insects of the order Hemiptera. The generic character is, that it has an inflected snout; the sheath is one-valved, three-jointed, and furnished with three bristles; it has neither jaws, feelers, nor lip; the antennæ are projecting, very short, submoniliform, clavate; the head is oblong, cylindrical above; the scutellum, which is as long as the abdomen, is depressed and membranaceous. There is but a single

Species.

CIMICOIDES, which is found in North America, and is rather less than the *Cimex erosus*: the body is of a ferruginous grey; the scutellum is of a pale ash colour with a yellow spot; the under wings are purplish-violet, and the fore-thanks are thickened.

MACROCEPHALUS, Μακροκεφαλος, compounded of μακρος, *great*, and κεφαλη, *head*, denotes a person with a head larger or longer than the common size.

Macrocephali, or *long-heads*, is a name given to a certain people, who, according to the account of authors, were famous for the unseemly length of their heads; yet custom so far habituated them to it, that instead of looking on it as a deformity, they esteemed it a beauty, and as soon as the child was born, moulded and fashioned its head in their hands to as great a length as possible, and afterwards used all such rollers and bandages as might seem most likely to determine its growing long.

MACROCERCI, the name established by Dr. Hill for a large genus of animalcules, distinguished from all others by having tails longer than their bodies. See **ANIMALCULE** and **VORTICELLA**.

MACROCENMUM, in *Botany*, from μακρος, *long*, and κνημη, *a leg*, alluding, as it seems, to the long stalks by which its clusters of flowers are supported. Browne Jam. 165. Linn. Gen. 90. Schreb. 120. Willd. Sp. Pl. v. 1. 933. Mart. Mill. Dict. v. 3. Juss. 200.—Class and order, *Pentandria Monogynia*. Nat. Ord. *Rubiaceæ*, Juss.

Gen. Ch. *Cal.* Perianth superior, of one leaf, turbinate, five-toothed, permanent; often bearing a foliaceous, stalked, internal appendage. *Cor.* of one petal, tubular; its limb small, in five ovate, slightly spreading segments. *Stam.* Filaments five, awl-shaped, villose, shorter than the corolla; anthers ovate, compressed, in the mouth of the flower. *Pist.* Germen inferior, conical; style simple, the length of the stamens; stigma thickish, two-lobed. *Peric.* Capsule oblong, somewhat turbinate, two-celled, and two-valved, bursting lengthwise, the partitions from the middle of each valve. *Seeds* numerous, imbricated, on a separate linear receptacle in each cell.

Eff. Ch. Corolla tubular, five-cleft. Capsule inferior, oblong, of two cells; the valves bursting longitudinally, with partitions from their centre. *Seeds* imbricated.

Obf. This genus is allied to *Cinchona*, but differs essentially in the structure of its capsule. Its great peculiarity consists in the large, leaf-like, coloured, stalked, solitary appendages, placed within the calyx, and according to Jacquin, in his *Hortus Schoenbrunensis*, originating from the very base of the germen, between two teeth of the calyx; but these, which might easily be mistaken for bractæas, are not found in every species, nor in every flower of any one. The original species is destitute of them.

1. *M. jamaicensis*. Linn. Sp. Pl. 244. Swartz. Obf. 68. t. 3. f. 1.—Corymbs on long axillary stalks. Calyx without an appendage. Native of shady places, about the banks of rivers, in the southern part of Jamaica. A branched smooth shrub, with long, lax, round scarred branches. *Leaves* opposite, stalked, a span long, elliptic-

oblong, pointed, entire, smooth, crowded about the ends of the branches; paler beneath. *Flowers* yellowish-green, in long-stalked corymbose panicles. *Fruit* near an inch in length.

2. *M. speciosum*. Jacq. Hort. Schonbr. v. 1. 19. t. 43.—Corymbs shorter than the leaves, hairy. Calycine bractæa roundish-ovate, its stalk shorter than the corolla.—Native of the Caraccas. Jacquin had it flowering in his stove in December. This is a most beautiful shrub, five feet high, its *inflorescence*, and even the *calyx* and *corolla*, downy or hairy, as well as the margins of the *leaves*. The axillary and terminal corymbose panicles compose a large tuft of flowers at the end of each branch, very conspicuous for the long purple-mouthed corolla, and the large rose-coloured, veiny, smooth or downy, appendage to the calyx of most of them, more splendid than the flowers themselves.

3. *M. candidissimum*. Vahl. Symb. v. 2. 38. t. 30.—Corymbs shorter than the leaves, smooth. Calycine bractæa roundish-ovate, its stalk longer than the corolla.—Found by Von Rohr in the neighbourhood of St. Martha.—This differs from the last in its smaller size, and white calycine bractæa, whose stalk exceeds the flower in length. The corolla is also of a shorter figure. *Capsule* elliptic-oblong, compressed.

4. *M. coccineum*. Vahl. Symb. v. 2. 38. t. 29.—Corymbs dense, the length of the footstalks, in long clusters. Calycine bractæa elliptical, its stalk much longer than the corolla.—Native of Trinidad. Von Rohr. A tree with hairy branches. The leaves are from one to two feet long, elliptic-obovate. Corymbs short and dense, disposed in very long clusters. One flower in each corymb is furnished with a very large, elliptical, long-stalked, scarlet calycine appendage, looking, at first sight, like a bractæa to each. The corolla is smooth, its limb nearly as long as its tube. *Germen* hairy.

5. *M. strictum*. Roxb. MSS.—Flowers in little dense, round, axillary heads, shorter than the footstalks.—Native of Bengal. Herb. Banks. The branches are smooth and angular. Leaves only two or three inches long, elliptical, pointed. Flowers small, without calycine bractæas.

Some species of this curious genus still, we believe, remain unsettled.

MACROCOLUM, or **MACROCOLLUM**, formed of μακρος, *large*, and κολλω, *I join*, among the Romans, the largest kind of paper then in use. It measured sixteen inches, and frequently two feet.

MACROCOSM, Μακροκοσμος, compounded of μακρος, *long*, *large*, and κοσμος, *world*, denotes the great world, that is, the universe.

In which sense it stands contradistinguished from *microcosm*, a term used to express man.

MACRODESPOUR, in *Geography*, a town of Bengal; 20 miles E.S.E. of Kishenagar.

MACROLOBIUM, in *Botany*, was so named, as Professor Martyn suggests, from having one of the petals very long in proportion to the others, but we are rather inclined to consider it as derived from μακρος, *large*, and λοβος, *a pod*; the large seed-vessel most evidently warranting such an application of the name, which was given by Schreber with Aublet's plates before him. Schreb. 30. Willd. Sp. Pl. v. 1. 186. Vahl. Enum. v. 2. 37. Mart. Mill. Dict. v. 3. (Outea; Aubl. Guian. 28. Juss. 347. Lamareck Illustr. t. 26.—Vouapa; Aubl. Guian. 25. Juss. 350. Lamareck Illustr. t. 26.)—Class and order, *Triandria Monogynia*. Nat. Ord. *Lomentaceæ*, Linn. *Leguminosæ*, Juss.

Gen. Ch. *Cal.* Perianth inferior, double; the outer of two, opposite, ovate-oblong leaves, adhering to the base of the

the inner, which is of one leaf, turbinate, short, with an oblique, five-toothed margin. *Cor.* Petals five, unequal; the upper one large, erect, unguiculate, oblong, obtuse, concave, undulated, inserted into the inner perianth; lower petals four, small, ovate, spreading, attached to the upper part of the inner perianth. *Stam.* Filaments four, one of them short, barren, standing under the large petal; the rest very long, thread-shaped; anthers square. *Pist.* Germen superior, stalked, ovate; style thread-shaped; stigma obtuse. *Peric.* Legume ovate, compressed, coriaceous, of one cell. *Seed* solitary, roundish, compressed.

Eff. Ch. Calyx double; the outer of two leaves; the inner turbinate and obliquely five-toothed. Corolla of five petals, unequal. Legume single-seeded.

Obs. Schreber remarks that *Outea* and *Vouapa* of Aublet do not seem to be distinct genera, as the corolla, fertile stamens and the pistil agree in number, form, and situation in both. In the former indeed, *Outea*, Aublet had never seen the ripe fruit, and in the latter he appears not to have distinguished the lesser petals from the calyx. Vahl, however, has kept these genera distinct, on the authority of Richard.

1. *M. pinnatum*. Willd. (*Outea guianensis*; Aubl. Guian. t. 9).—Leaves pinnate, obtuse.—Native of woods and forests in Guiana, flowering in May. The trunk of this tree rises to the height of fifty feet, and is about a foot in diameter. Bark smooth and greyish. Wood whitish towards the surface, but red at the heart. Branches spreading, inclining, the upper ones erect. Leaves abruptly pinnate, alternate; leaflets four, ovate, obtuse. Stipules two, acute, small, deciduous, at the base of the common stalk. Flowers in spikes, axillary, of a violet colour. Some eminent botanists have suspected that this may be a *Tamarindus*, and the following a *Hymenæa*.

2. *M. hymenæoides*. Willd. Vahl. (*Vouapa bifolia*; Aubl. Guian. t. 7).—Leaves binate, pointed, oblique at the base. Legume oblong. Found in the woods of Guiana and Cayenne, near the shores of lakes and rivers, flowering in November and bearing fruit in January.—A tree sixty feet high, much branched at the top. Leaves alternate, of two green, strong, and thick, oval, long-pointed leaflets. Flowers in solitary, terminal clusters from the bosom of the leaves, of a pale violet colour.

3. *M. sphaerocarpum*. Willd. Vahl. (*Vouapa Simira*; Aubl. Guian. t. 8).—Leaves binate, pointed, ovate. Legume roundish compressed.—Native of woods at Courou, in Guiana, bearing fruit in June. The height of this tree is eighty feet. Trunk thick, much branched at the top. Leaves alternate of two ovate, entire leaflets, reticulated with veins. The flowers have not been seen, but the fruit grows in axillary clusters, and is a thick, roundish, leathery, ferruginous legume, of one cell and two valves, containing a solitary, roundish, depressed, smooth seed. The wood is violet-coloured.

MACROLOGY, *μακρολογία*, formed of *μακρος*, long, and *λογος*, discourse, in *Rhetoric*, a redundant, or too copious style; an example of which we have in Livy, lib. viii. "Legati non impetrata pace, retro domum, unde venerant abierunt."

The too copious is equally subject to obscurity with the too concise style, and consequently ought to be avoided. See **BRACHYOLOGY**, **DICTION**, and **STYLE**.

MACRONISI, in *Geography*, a small island in the Turkish Archipelago, near the coast of Livadia; formerly called Helena, because it is said to have afforded an asylum to that princess. It was anciently very populous, but is now deserted, and only occupied by lizards or other reptiles. In

the interior parts are found many rare plants; 6 miles N.E. of cape Caloni. N. lat. 37° 38'. E. long. 24° 17'.

MACROPEDIUM, the *long-legs*, a name given by some writers in natural history to the common tipula.

MACROPIPER, a name given by authors to the *piper longum*, or long pepper.

MACROPNUS, formed of *μακρος*, long, and *πνοη*, breath, a word used by Hippocrates, and other old writers in medicine, to signify a person who fetches his breath at long intervals. It is used in opposition to *brachypnus*, or short-breathed.

MACROPTERA, derived from *μακρος*, long, and *πτερον*, a wing, in *Ornithology*. The hawks of this genus have their wings so long, that when closed they reach to the end of the tail, or nearly so. Of this genus are the bald-buzzard, the kite, the hen-harrier, the honey-buzzard, and the common buzzard, the sacre, the jersfalcon, &c.

MACROPUS, **KANGUROO**, in *Natural History*, a genus of the class and order Mammalia-feræ. The fore-teeth in the upper jaw six, and emarginated; but in the young animal they are eight; there are only two in the lower jaw, very large, long, sharp, and pointing forwards: there are five grinders on each side, both in the upper and lower jaw, distant from the other teeth; the fore-legs are very short; and the hind ones very long; the female has an abdominal pouch. There are two species, viz. the major, or *M. giganteus*, answering to the *Didelphis gigantea* of Linnæus; and the *M. minor*, or the kangaroo rat.

This genus, as it appears from what has been said, has hitherto been generally confounded with the *Didelphis*, which see: it is, however, found essentially to disagree with that genus in respect to the teeth and other particulars: hence Dr. Shaw, and other later naturalists, have separated it from the *Didelphis* tribe.

Of all the animals which the continent of Australasia has presented to our view, the *Platypus* excepted, (which see) the kangaroo must be considered as the most extraordinary: "its size, conformation, teeth, and other particulars, conspiring to render it a most interesting object to every naturalist."

Species.

MAJOR; Great kangaroo. Brownish, with sharp ears and pentadactylous fore feet. This animal was first discovered by captain Cook's people, while at Botany Bay, in New Holland, in the year 1770, an interesting account of which is given in the captain's first voyage. It is thus described by Dr. Shaw: "The general size of the kangaroo is at least equal to that of a full-grown sheep: the upper parts of the animal are small, while the lower are remarkably large in proportion; yet such is the elegance of gradation in this respect, that the kangaroo may justly be considered as one of the most picturesque of quadrupeds. The head bears some resemblance to that of a deer, and the visage is mild and placid; the ears are moderately large, of a sharpened form, and upright; the eyes large; and the mouth rather small; the neck is thin and finely proportioned; the fore-legs are extremely short, with the feet divided into five toes, each of which is furnished with a sharp and somewhat crooked claw. From the breast downwards the body gradually enlarges, and again decreases a little towards the tail; the thighs and hind-legs are extremely stout and long; and the feet are so constructed as to appear, at first sight, to consist of but three toes, of which the middle one is by far the largest, and is furnished with a claw of great size and strength; the exterior toe is also furnished with a very strong claw, but far smaller than that of the middle; and the interior consists of two small toes united under a common skin, with their respective claws placed so close to each other

other as to appear like a split or double claw: the whole appearance of the foot bears a distant resemblance to that of a bird. The great kangaroo rests on the whole length of the foot, which is callous, blackish, and granulated beneath. The colour of the animal is an elegant pale brown, lighter, or more inclining to whiteness on the abdomen; the ventral pouch, or receptacle for the young, is situated as in the didelphis tribes, and is extremely large and deep." The dimensions of a full-grown kangaroo are these: eight feet from the tip of the nose to that of the tail; length of the tail three feet one inch; of the head eleven inches; of the fore-legs two feet; of the hind three feet seven inches; circumference of the fore-part of the animal, near the legs, three feet nine inches; of the lower part, near the legs, four feet five inches; round the thickest end of the tail thirteen inches. The weight of the largest specimens is said to be 150lbs., but it is thought to attain a still larger size. "Though the general position of the kangaroo, when at rest, is standing on its hind-feet, yet it frequently places its fore-feet on the ground also, and thus feeds in the manner of other quadrupeds. It drinks by lapping. In its natural state it is extremely timid, and springs from the sight of mankind by vast bounds of many feet in height, and to a surprising distance. The female kangaroo has two mammae, situated in the abdominal pouch, and on each side are seated two teats; yet, so far as has hitherto been observed, the animal produces but one young at a birth, and so exceedingly diminutive is the young, when first found in the pouch, as scarcely to exceed an inch in length. The young continues in the pouch till it is grown to a large size, and takes occasional refuge in it long after it has been accustomed to come abroad. It feeds on vegetable substances, and chiefly on grass. In their native state, kangaroos are said to feed in herds of thirty and forty together, and one is usually stationed, as if apparently on the watch, at a distance from the rest. One of the most remarkable peculiarities of this animal is its power of separating at pleasure, to a considerable distance, the two long fore-teeth in the lower jaw. The *Mus maritimus*, it must be observed, does the same. It is thought that there are several varieties of the great kangaroos; some being of a much darker colour than the common kangaroo described, and have a coarser fur. This animal may now be considered as, in a great degree, naturalized in England; several having been kept some years in Richmond park, where they have bred. The flesh of the kangaroo is coarse, and will not be eaten as a luxury; but will serve in case of scarcity to persons in their foreign travels.

MINOR, Lesser, or brown kangaroo. Ash-coloured beneath, with rounded ears, and tetradactylous fore-feet. This species of animal has, from its colour and general aspect, obtained the title of kangaroo-rat; it is about the size of a rabbit; the tail is long, tapering, hairy; hind-legs long, three-toed; ears rounded; eight upper fore-teeth, the two middle ones sharper; the lower two long and pointed; three grinders on each side, the fore-most channelled; fur smooth, dark-brown. The structure of the hind-feet in this species perfectly resembles that of the great kangaroo. The female is furnished with an abdominal pouch for the reception of the young. Some of this species were imported in a living state from New Holland.

MACRORYNCHÆ, *long-beaked*, derived from μακρός, *long*, and ῥιγχος, *a beak*, in *Ornithology*, the character of a large order of the bird kind.

The birds of this order have all of them beaks many times longer than their heads, with oblong nostrils, and a furrow running from them towards the apex of the beak.

MACROTELOSTYLA, in *Natural History*, the name of a genus of crystals, which are composed of two pyramids, joined to the end of a column; both the pyramids, as also the column, being hexangular, and the whole body consequently composed of eighteen planes.

The word is derived from the Greek μακρός, *long*, τελειος, *perfect*, and στυλος, *a column*; expressing a perfect crystal with a long column.

There are only three known species of this genus. Either of the sorts found with us, are called by the common name of *Cornish diamonds*.

MACROULE, in *Ornithology*, the name given by many to the largest species of coot. It is of a deeper black than the common kind, and has a large bald spot on its head. It is also called by some *diable de mer*. It is found in Lancashire and Scotland. See *FULICA Aterrima*.

MACROURUS, in *Natural History*, a genus of fishes of the order Thoracici. There is but a single species, which is reckoned by Gmelin as belonging to the genus CORYPHÆNA. We have, however, in that article, given reasons why it cannot be admitted in that tribe; instead, therefore, of denominating the fish under consideration the CORYPHÆNA *Rupestris*, we follow Dr. Shaw, and others, in naming it the

MACROURUS *Rupestris*, or Long-tailed Imminet, of which the generic character is, head large, eyes large; body at the hind part attenuated into the tail.

The head of this remarkable fish is large and thick: the upper jaw projecting above into the form of an obtuse snout; the eyes are very large, the mouth wide, with five rows of small curved teeth in the upper jaw, and two rows in the lower; the tongue is white, thick, short, and cartilaginous; beneath the tip of the lower jaw hangs a beard or cirrus; the body tapers from the middle part, and at length is continued into a very long, slender, and pointed tail; the whole fish is covered with moderately large rounded scales, each of which is furnished with a strong toothed carina, ending in a pointed tip, which causes a remarkable roughness of surface; so that the hand is wounded by drawing it over the fish from the tail towards the head. The first dorsal fin is situated near the middle of the back, and is furnished with nine or ten rays. The second dorsal fin commences at a small distance from the first, and running to the tip of the tail is united with the vent fin, which is likewise continued from the tip of the tail to the vent, near the middle of the body. The colour of this fish is a silvery-grey, deepest on the upper parts; its usual length is about three feet, but is occasionally seen of a larger size. It is a native of the Northern seas, and is mostly found about the coasts of Greenland and Iceland, and is numbered among the edible fishes of the Greenlanders. It swims swiftly, and when first taken, it struggles with great violence, endeavouring to defend itself by lashing with its tail; its large eyes projecting, at the same time, to a surprising degree. It is known in some places by the name of Berg-lax, or Mountain Salmon; and the Greenlanders call it "Ingminnet," from which the English generic name has been taken. Shaw's Zoology.

MACSOUD-BEGUI, in *Geography*, a town of Persia, in the province of Irak; 54 miles E. S. E. of Ispahan.

MACSWINE'S BAY, a bay of Ireland, in the N. part of Donegal bay; 11 miles W. of Donegal. N. lat. 54° 36'. W. long. 8° 17'.

MACTEN, one of the smaller Philippine islands, in which, as some say, Magellan was killed. N. lat. 10° 30'. E. long. 123 48'.

MACTRA, in *Natural History*, a genus of the class Vermes, and order Testacea, is thus described: the animal is

a *Tethys*, which see; shell bivalve, unequal-sided, equivalve; middle tooth of the hinge complicated, with a small hollow on each side, lateral ones remote, and inserted into each other. There are twenty-seven species inhabiting the coasts of all quarters of the world, and four of them, as will be noticed by asterisks in the article, are found on our own coasts. They are of different sizes, from that of a man's hand, downwards, so that some of them are scarcely an inch broad. The shells are likewise exceedingly different, some being smooth, others wrinkled; some are wedge-shaped, others ovate; they are also diaphanous, pellucid, and semi-transparent; some are striate, banded, white or fawn-coloured, and some resemble a *tellina*, others a *mya*. The following is a brief enumeration of the several

Species.

SPENGLERI. The shell of this is smooth, with a flat anterior margin, on which is a lunate gape; it is found at the Cape of Good Hope, nearly as large as a man's hand, and is a little gaping, pale, sub-diaphanous, sub-triangular. The gape, before the hinge, is lunate, acute, and reaching to the hollow of the hinge; the beaks are incurved, and the teeth of the hinge triangular.

PLICATORIA. Shell with transverse wrinkled plaits, diaphanous; the anterior margin is flattish; behind the beaks is a compressed oblong gape. It is found in the Indian ocean, and is from one to two inches long, and two inches and a half broad. The shell of this species is thin as paper, with smooth lanceolate depressions on each side the hinge; the anterior one flattish, with a ridge near the beaks; the posterior impressed, and more ovate; beaks incurved; lateral teeth of the hinge composed of two parallel membranes.

PAPYRACEA. Shell very thin, pellucid, and white; it is convex, the fore-part a little gaping, very finely striate, and ribbed. It is found in the Nicobar islands, but is extremely rare; it resembles the last, but is more convex and unequal-sided; except in the hinge, it is very like a *tellina*.

STRIATULA. The shell is smooth and diaphanous; the beaks are substriate, with a smooth marginal impression before them, surrounded with a rim. It inhabits the Comandel coasts, and is found also in the Mediterranean, is about two inches and a half long, and three inches broad; it is white, sub-triangular, rather convex, a little gaping on the fore-margin.

STRIATA. The shell is thick and triangular, with strong, thick, crowded, smooth, arched striæ; it is white, and glabrous within at the beaks. Is found in the Mediterranean, and is about the size of the last.

GLABRATA. This species has a smooth, diaphanous, and striate shell; the beaks are very smooth; and the margins on each side are striate. It is found in the African and Indian oceans; is about the size of the *Striata*; the colour is white; beaks smooth, and striate on the border.

ROTUNDATA. Shell obtusely triangular, whitish, with milk-white bands on the beaks; the margins, on each side the beaks, are violet. It inhabits the Mediterranean, and is of the same size as the last.

NITIDA. The shell is snowy and diaphanous; the depressions on each side the beaks are striate; the anterior ones marked with a ridge. The shell is triangular, and the beaks retroverted and distant.

CORALLINA. This is an inhabitant of the Mediterranean and Guinea seas; the shell is smooth, sub-diaphanous, and white with paler bands; it is about two inches broad, and an inch and a half long, triangular, with obtuse depressions on each side the beaks.

LACTEA. The shell is thin, pellucid, white, and the

fore-part very finely striate, with paler bands. It is found in the Indian ocean; it resembles the last, but is thinner, and more convex; the anterior part is flattish, with an obtuse margin.

* **STULTORUM.** The shell is semi-transparent, smooth, and glossy; it is obsoletely radiate, white without; and purplish within. This is found on the shores of our own country, and also in the American seas; and is only the size of a hazel-nut; the shell is convex, somewhat triangular, brown, testaceous or cinerous, with or without faint rays.

GRANDIS. Shell semi-transparent, smooth, fawn-colour, with pale rays; the beak and hinge placed beyond the middle. This is very like the last; is more than three inches broad; and two broad, gaping at the extreme angle; the anterior side more produced.

* **SOLIDA.** Shell opaque, and smoothish; found very commonly on the European shores; the shell is thick, strong; colour white, to a yellowish-brown, frequently marked with blue or pale orange belts; while alive it is smooth, and when dead it has a few high transverse striæ, like ribs; the lateral teeth are small, elongated with a large hollow; the middle tooth is small.

* **LUTRARIA.** The shell is oval-oblong and smooth, without lateral teeth. It inhabits the European coasts, near the mouths of rivers; it resembles a *mya* gaping at both ends; in colour it is of a dirty-white, or yellowish tinged with orange, and irregularly clouded with brown; hinge with a small and large triangular cavity in one valve, and a similar cavity with an elevated triangular tooth in the other.

CYGNUS. Shell snowy, thick, and three-sided, very finely striate transversely; the fore-part is flattish, and slightly wrinkled; behind the beaks a broad, heart-shaped, thinly striate impression. It is found on the coasts of Tranquebar; an inch long, and rather more than an inch broad.

MACULATA. Shell obtusely triangular, smooth, thin, with pellucid chefnut spots; within white, and very finely striate.

TURGIDA. The shell of this species is inflated, faintly striate, of an ochre colour, but white within; the beaks are distant purplish; the hinge has a supernumerary triangular double tooth. It inhabits Tranquebar, and is nearly three inches long, and more than that broad; it is thin, pellucid, finely striate, and wrinkled before and behind.

VIOLACEA. Shell thin, obsoletely radiate, finely striate transversely; margins on each side the beaks whitish; hinge with a supernumerary double triangular tooth. This is found on the coasts of Tranquebar, and is about two inches long, and three broad. The shell is thin brittle, gaping here and there, the anterior margin oblong, elevated, and wrinkled.

CUNEATA. Shell wedge-shaped, blue, finely striate transversely; the margin crenulate within; it resembles in many respects the last, but is only an inch long, and not so much as that broad; it is sometimes white.

GLAUCA. The shell of this is ovate, dirty-white, with glaucous rays, very finely striate transversely; the anterior part wrinkled. It inhabits the Mediterranean; the same size as the *Turgida*; the beaks are turned backwards, with a narrow gape between them.

PELLUCIDA. Shell ovate, thin, and of a pellucid white, with unequal transverse striæ. It inhabits Guinea; is not two inches long, but rather more than this broad; the shell is brittle, a little produced forwards, and gaping.

FRAGILIS. In this the shell is ovate, thin, smooth, pellucid, flattish; the anterior gape transversely striate, and wrinkled. It inhabits the Nicobar islands, and resembles the last; the shell is gaping, and slightly plaited on the fore-

fore-part; the margin is acute, subangular before and rounded behind.

RUGOSA. Shell ovate, dirty-white, with elevated longitudinal striæ crossing the transverse ones, which are a little more raised. It is thick and white within, and is about two and a half inches long, and the same in breadth.

NICOBARICA. Shell ovate, thin, and pellucid on the fore-part; the hind-part with cancellate striæ. Found in and about the Nicobar islands.

COMPLANATA. In this the shell is ovate, thin, with arched plaits; the plaits transversely striate. It inhabits India, and is of a blueish colour, but sometimes white, is an inch long, and two and a half broad.

* **LISTERI.** Shell very thin, nearly round, whitish; hinge with a triangular tooth, and large pyriform hollow. Found at the mouth of the river Tees; rather larger than the last.

PIPERITA. Shell ovate, compressed, transversely striate; teeth of the hinge very minute, with a large oblique hollow. Inhabits the Mediterranean; about two inches long and one and a half broad.

MACUCAGUA, in *Ornithology*, the name of a Brazilian bird of the gallinaceous kind, called also by some the *gallina sylvestris*, or wild hen. It has no tail: but is a very well tatted fowl, and has twice as much flesh as the European hen; its eggs are somewhat larger than the common hen eggs, and of a blueish-green colour; it feeds on fruit that falls off the trees, &c. and runs well, but cannot fly high or far, and never is seen in the trees. Marcgrave. See *TE-TRAO Major*.

MACUIH-YU, in *Geography*, a small Chinese island, belonging to the province of Quang-tong. N. lat. 23° 10'. E. long. 116° 32'.

MACUL, a town of Chili; 15 miles S.E. of St. Yago de la Nouvelle Estramadura.

MACULA, a sea-port of Arabia, in the province of Hadramaut; 150 miles N.E. of Aden.

MACULA, in *Medicine*, a *spot*, is a term principally used to denote those detached efflorescences of the skin, or discoloured patches, of various dimensions and figures, which appear without any considerable elevation or protuberance above the rest of the surface, and with large interferences of the natural colour. The term includes, therefore, those congenital discolourations, which are called *mother-spots*, or technically *nevi materni*, and which are commonly attributed, without any foundation, to frights or other affections of the mind or imagination of the mother; as well as *moles*, *petechia*, *freckles*, &c. See *IMAGINATION*.

The *macule hepatica*, or *liver-spots* of the older authors on medicine, are little else than large freckles; consisting of patches of various sizes, affecting chiefly the breast, shoulders, and groins, of a brown colour, and accompanied with a slight roughness of the surface, in consequence of the formation of minute branny scales, in which the cuticle partially exfoliates. In the arrangement of cutaneous affections adopted by Dr. Willan, these spots are comprehended in the order of *scaly diseases*, under the title of *PTYRIASIS*; which see.

The *macule volaticæ* of authors, which occur in infants during dentition, are varieties of the eruption, popularly denominated the *red-gum*, the *STROPHULUS* of Dr. Willan. See that article; also *DENTITION*, and *INFANTS, Diseases of*.

The last mentioned author has constituted an order of *macula* in his arrangement, which includes those chronic affections of the skin, that are unaccompanied by scales, pimples, rashes, vesicles, pustules, or tubercles, which characterize the other orders. It comprehends principally, there-

fore, the *ophelides* and freckles, *navi*, moles, and other original marks. The removal of these spots is sometimes accomplished by surgical means; but they are merely local, and beyond the controul of medicine. See *NÆVUS*, &c.

MACULA Oculi, a word used by many authors to signify a cataract or suffusion.

MACULÆ, in *Astronomy*, dark spots appearing on the luminary faces of the sun, moon, and even some of the planets.

In which sense *macula* stand contradistinguished from *facula*.

The *solar macula* are dark spots of an irregular, changeable figure, observed in the face of the sun, first taken notice of by Galileo, 1610, soon after he had finished his telescope, and afterwards accurately observed by Scheiner, Hevelius, Mr. Flamsteed, Cassini, Kirch, &c. Phil. Trans. vol. i. p. 274. vol. lxiv. p. i. p. 194.

Many of these maculae appear to consist of heterogeneous parts; of which the darker and more dense are called by Hevelius nuclei, and are encompassed, as it were, with atmospheres somewhat rarer, and less obscure; but the figure both of the nuclei and entire maculae is variable. In 1644, Hevelius observed a small thin macula, which, in two days time, grew to ten times its bulk; appearing withal much darker and with a larger nucleus, and such sudden mutations are frequent. The nucleus, he observed, began to fail sensibly before the spot disappeared; and that, before it quite vanished, it broke into four, which, in two days, again re-united. Some maculae have lasted two, three, ten, fifteen, twenty, thirty, but seldom forty days; though Kirchius observed one in 1681, which remained from April 26th to the 17th of July. The spots move over the sun's disk with a motion somewhat slacker near the limb than the centre: that observed by Kirchius was twelve days visible on the sun's disk; for fifteen days more it lay behind it, it being the usual rule to return to the limb whence they departed in twenty-seven, sometimes in twenty-eight days.

Lastly, it must be observed, that the maculae contract themselves nearer the limb, and in the middle of the disk appear much larger; those often running into one in the disk, which in the limb were separate: that many of them arise in the middle of the disk, and many disappear in the same: and that none of them are observed to deviate from their path near the horizon; whereas Hevelius, observing Mercury in the sun near the horizon, found him too low, being thrust twenty-seven seconds beneath his former path.

From these phenomena we collect, 1. That since Mercury's depression below his path arises from his parallax, the maculae, having no parallax from the sun, are nearer him than that planet.

2. That, since they arise and disappear in the middle of the sun's disk, and undergo various alterations with regard both to bulk, figure, and density, they must be formed *de novo*, and again dissolved about the sun; and hence some have inferred, that they are a kind of solar clouds, formed out of its exhalations.

3. If they are of this nature, as they rise over his body and are suspended at a certain height from it, it appears, from the laws of hydrostatics, that the sun must be encompassed with some fluid to drive those exhalations upwards; which fluid must be denser as it is lower, and rarer as higher, like our atmosphere: and, since the maculae dissolve and disappear in the very middle of the sun's disk, the matter thereof, supposing them to be solar exhalations, must fall back again to the sun; whence there must arise changes in the sun's atmosphere; and consequently in the sun itself.

4. Since the revolution of the maculæ round the sun is very regular, and since their distance from the sun is very small, it is not properly the maculæ that move round the sun, but it is himself, together with his atmosphere, where in the maculæ swim, that in the space of twenty-seven days, twelve hours, twenty minutes, moves round his own axis; and to the same fixed star in twenty-five days, fifteen hours, sixteen minutes (see SUN); and hence it is, that the maculæ, being viewed obliquely near the limb, appear narrow and oblong.

5. Since the sun appears with a circular disk in every situation, his figure, as to sense, must be spherical.

The magnitude of the surface of the spot may be estimated by the time of its transit over a hair in a fixed telescope. Galileo reckons some spots to be larger than all Asia and Africa put together: but if he had known the sun's parallax and distance as exactly as we do, he would have found them much larger than the whole surface of the earth. For, in 1612, he observed a spot so large as to be plainly visible to the naked eye; it, therefore, subtended an angle at the eye of about a minute. The diameter of the earth, if removed to the sun, would subtend an angle of but about seventeen seconds. Therefore, the diameter of the spot was to the diameter of the earth as sixty to seventeen, or three one-half to one, nearly; and consequently, the surface of the spot, if circular, to a great circle of the earth as twelve one-fourth to one, and to the whole surface of the earth as twelve one-fourth to four, or nearly three to one. Gassendus observed a spot whose diameter was $\frac{2}{3}$ th of the sun's, and, therefore, subtended an angle at the eye of above a minute and a half. Its surface was, therefore, above six times larger than the whole surface of the earth. He tells us, that he saw above forty spots at once, but did not perceive that the light of the sun was sensibly diminished: nevertheless, the paleness of the sun mentioned by historians, after the death of Julius Cæsar, might have been caused in this manner, if we admit the fact.

The opinions that have been formed concerning the nature, origin, and situation of the solar spots, have been various: Dr. Wilson, professor of practical astronomy in the university of Glasgow, by attending particularly to the different phases presented by the umbra, or shady zone, of a spot of an extraordinary size that appeared upon the sun, in the month of November, 1769, during its progress over the solar disk, was led to form a new and singular conjecture concerning the nature of these appearances; which he seems to have afterwards confirmed by repeated observations. The results of these observations are, that the solar maculæ are cavities in the body of the sun; that the nucleus, as the middle or dark part has been usually called, is the bottom of the excavation; and that the umbra, or shady zone usually surrounding it, is the shelving sides of the cavity. Dr. Wilson appears not only to have very satisfactorily ascertained the reality of these immense excavations in the sun's body, but has pointed out a method of measuring the depth of them. He estimates, in particular, that the nucleus, or bottom of the large spot above mentioned, was not less than a semidiameter of the earth, or about four thousand miles, below the level of the sun's surface; while its other dimensions were of a much larger extent. He observed, that when a spot in the middle of the sun's disk, where it is surrounded equally on all sides with its umbra, comes near the western limb of the sun; that part of the umbra, which is next to the sun's centre, gradually diminishes in breadth, and at length, when the spot reaches within about a minute of the limb, totally disappears; while the umbra, on the other side of it, continues nearly of its former dimensions.

If, after the period of half a revolution, the spot appears again on the opposite side of the disk, that part of the umbra, which had before disappeared, and which is now on the left hand side of the nucleus, is now plainly to be seen: but the umbra on the other side of the spot, or that which is next to the sun's centre, seems to have vanished in its turn; being hid from the view by the upper edge of the excavation, or by the oblique position of its sloping sides, with respect to the eye. As the spot, however, advances on the sun's surface, this umbra, or side of the cavity, comes in sight; it first appearing narrow, but afterwards gradually increasing in breadth, in proportion as the spot moves toward the middle of the disk. These appearances, in particular the gradual diminution and disappearance, as well as the re-appearance and gradual enlargement of the umbra, on the one side or the other of a spot, according as it advances near the western limb, or proceeds onwards from the eastern edge of the sun, are naturally accounted for by Dr. Wilson's supposition, that the umbræ are the sloping sides of a cavity, which will appear under different angles, or of different breadths, or totally disappear, according to their position with respect to the eye of the spectator. These appearances, at least, perfectly resemble the phases that would be exhibited by an excavation in a spherical body, made to revolve on its axis; the bottom of the cavity being painted black, and the sides lightly shaded. From these and other observations it may be inferred, that the body of the sun, at the depth of the nucleus, either emits no light, or emits so little as to appear dark, when seen at the same time, and compared with that resplendent, and probably, in some degree, fluid substance that covers his surface. This manner of considering these phenomena naturally gives rise to many curious speculations and inquiries. It is natural, for instance, to inquire by what great commotion this refulgent matter is thrown up on all sides, so as to expose to our view the darker part of the sun's body, which was before covered by it? What is the nature of the shining matter? and why, when an excavation is formed in it, is the luitre of this shining substance, which forms the shelving sides of the cavity, so far diminished as to give the whole the appearance of the shady zone, or darkish atmosphere surrounding the denuded part of the sun's body? On these and many other subjects, Dr. Wilson has advanced some ingenious conjectures; for which we must refer the curious to the Phil. Transf. vol. lxiv. part i. art. 1. See also some remarks on Dr. Wilson's Theory, by Mr. Woolaston, in the Phil. Transf. vol. lxiv. part ii. art. 1. p. 337, &c.

M. de la Lande, in the Memoirs of the French Academy for 1776, contends, that the spots of the sun are owing to dark bodies like rocks, which by an alternate flux and reflux of the liquid igneous matter of the sun, sometimes raise their heads above the general surface; and that that part of the opaque rock, which at any time thus stands above, gives the appearance of the nucleus, while those parts which in each lie only a little under the igneous matter, appear to us as the surrounding umbra. See this opinion examined, and Dr. Wilson's vindicated by himself, in Phil. Transf. vol. lxxii. pt. i. art. 10.

Dr. Herschel thinks that the sun is an opaque body, possibly inhabited, covered with an atmosphere in which clouds of a luminous nature are floating, and that the spots are interruptions of these clouds. Of these clouds, as he conceives, there are two strata, the upper of which only is luminous, and the lower stratum, as he supposes, protects the body of the sun from their heat. Phil. Transf. for 1795, vol. lxxxv. p. 46, &c.; and in Phil. Transf. for 1801, p. 265. 354, he endeavoured to shew that the variations of heat

Heat of different years is owing to the more or less copious supply of fuel in the sun, which constitutes his spots. See FACULÆ, SPOTS, and SUN.

MACULPA, in *Geography*, a town of Mocaumpour; 20 miles S. of Batjan.

MACUMBA, a country of Africa, forming the southern province of Mocaranga.

MACUNA, in *Botany*. See DOLICHOS.

MACUNA, in *Geography*, one of the Navigator's islands, in the South Pacific ocean, where several of M. de la Peoufe's crew were massacred by the inhabitants. S. lat. 14° 19'. W. long. 169°.

MACUNGY, a township of America, in Northampton county, Pennsylvania, containing 1844 inhabitants.

MACUPA, a town of Africa, in the country of Mambaça, near the coast; five miles N.W. of Mambaça.

MACURITAS, a town of the island of Cuba; 115 miles W.S.W. of Havanna.

MACUTA, in *Commerce*, a money of account in Guinea, on the coast of Africa, equal in value to 2000 small shells, called cowries, or zimbis. The Sierra Leone Company use pieces of 10, 5, 2, and 1 macutas. The first weighs 16 dwt. 21 gr. contains, in pure silver, 330.8 gr. and is worth 3s. 10¼d. sterling. The second weighs 8 dwt. 13 gr. contains, in pure silver, 167.6 gr. and its value is 1s. 1¼d. sterling. The third weighs 3 dwt. 7½ gr. contains, in pure silver, 65 gr. and is worth 9d. The fourth weighs 1 dwt. 16 gr. contains, in pure silver, 32.5 gr. and its value is 4¼d. sterling. The 10 macuta piece, or dollar, has on one side two joined hands, with the figures 100 both above and under them, and the inscription "one-dollar piece;" on the reverse, a lion; legend over the lion, SIERRA LEONA COMPANY, and under it, AFRICA. The half-dollar is marked 50; the ¼ dollar, 20; and the ⅕ dollar, 10; with the inscriptions, HALF-DOLLAR PIECE, TWENTY-CENT PIECE, and TEN-CENT PIECE: the rest as on the dollar.

MAD, in *Geography*, a town of Hungary; five miles N. of Tokay.

MAD, a river of America, called also "Pickawa Fork," which is a rapid branch of the Great Miami, that passes in a beautiful stream with a S.W. course through a pleasant level country of very great fertility.

MAD-Apple, or *Melongena*, in *Botany*. See SOLANUM.

This plant is propagated in the gardens of the curious with us; and in Spain, Italy, and Barbary, common in the kitchen-gardens, the fruit of them being frequently eaten there, boiled with fat flesh, putting thereto some scraped cheese, and preserving it through the winter with vinegar, honey, or salt pickle. This they esteem of great efficacy to provoke venery. In summer also, when the fruit is just ripe, they eat it fresh dressed, with spices, and other ingredients.

The apples being much like those of the mandrake, have induced some moderns to suspect this plant to be the male mandrake of Theophrastus; and supposing them to be deadly to call them mad-apples; whereas in reality they excite no symptoms of madness, but are used by the Italians and Spaniards in their sauces and sweatmeats. They have the taste of the citron.

MAD-Dog. See DOG and HYDROPHOBIA.

MAD-Water, among *Miners*, is water that has been drawn from a shaft, or any part of the mine, and returns back again to the same place from whence it was drawn.

MAD-Word, in *Botany*. See ALYSSUM.

MAD-Word, *German*. See ASPERUGO.

MADABLOTA. See GERTNERA.

MADAGASCAR, in *Geography*, an island in the Indian sea, separated from the coast of Africa by the channel

of Mozambique. Its length is stated by De Pagés to be about 900 miles and its breadth 100; but others assign to it 840 geographical miles in length, and about 220 in medial breadth. De Pagés says, that next to Borneo, it is the most extensive in the world. He might also have excepted Papua and New Holland, if the latter may be classed in the number of islands. As it extends from N.N.E. to S.S.E. from the 12th to the 26th degree of south latitude, its climate is mild and agreeable. Of its first discovery, nothing certain is known. The ancients, even as late as Ptolemy, seem to have been unacquainted with it. The first mention of it, upon which we can depend, is by Marco Polo, in the 13th century, who having derived his knowledge of it from the Arabs, describes it by its present name. It escaped the notice of Gama, who coasted along the African shore; and though it is said to have been known to the Arabs and Persians from time immemorial, under the name of "Sarandib," its first discovery is ascribed to Lorenzo, or Lawrence Almeyda, in the year 1506. Hence the Portuguese gave it the name of St. Lawrence; the French, in the reign of Henry IV., called it Isle Dauphiné: its real name, however, is Madecassa, though it is now generally known by that of Madagascar. It is divided into 28 provinces; and its surface, according to Rochon, may be estimated at 200 millions of acres of good and arable ground, celebrated for fertility and for the variety of its productions. All its different parts are watered by torrents and large rivers, and more especially by a number of smaller rivulets, which flow from the vast ridge of mountains that separates the eastern from the western coast. Vigagora is the highest mountain in the N., and Botitmena in the S. These mountains contain in their bowels precious minerals and curious fossils, and their summits are crowned with lofty trees, of long duration. The scenery which the island presents is very picturesque and interesting, as it is diversified with precipices, cataracts, and immense forests. The vegetation of its hills and plains experiences no obstruction from the vicissitude of the seasons, nor does it derive much assistance from the labour of the inhabitants. The spacious commons afford pasture to numerous droves of oxen and flocks of sheep: and the soil evinces its fertility, with little aid of culture, by yielding a crop of rice in the proportion of 100 grains to one that is sown. The woods afford a prodigious variety of trees, such as all kinds of palm trees, woods used in dyeing, ebony, bamboos of an enormous thickness, as well as orange and lemon trees. They also supply timber for building ships and houses. Flacourt says, that in the year 1650 he sent to France 52,000 aloe trees of the first quality; and he has given the names of two or three hundred different plants. Of late there have been obtained from this island the Mauritanian mulberry with green fruit, and the Gummiphera Madagascariensis, the juice of which, called by the islanders "finguiera," concretes into an elastic gum, similar to the caoutchouc of Cayenne. Of esculent plants this island furnishes not only rice in abundance, but the banana, yam, nymphæa lotos, several fruits of dolicho or kidney beans, gourds, water melons, and cocoa nuts. The fruits are pine apples, tamarinds, oranges, and pomegranates. The spices and other condiments are common and betel pepper, ginger, turmeric, cinnamon, and sugar. The Indian fig grows, as well as cotton and indigo. Many quadrupeds are peculiar to this island, whence some naturalists have, perhaps, too hastily inferred, that it never joined the African continent. Here are no lions, tigers, elephants, nor horses. Many of the most valuable minerals might be supplied from hence; such as the purest rock crystal, beds of which occur, gold ore, topazes, sapphires, emeralds, and

MADAGASCAR.

Spotted jasper, or blood stones. Here are found numerous black tourmalins of Haüy, which the ancient mineralogists considered as the schorl of Madagascar. The inhabitants of Madagascar, who call themselves "Malegashes," or "Madecasses," are in general well-shaped, and above the middling size: the colour of their skin is various; some tribes being of a deep black, others tawny; some having a copper complexion, but the greatest number being of an olive colour. All those that are black have woolly hair, like the negroes of the coast of Africa. The hair of those who have the complexion of Indians or Mulattoes, does not frizzle more than that of the Europeans; their nose is not flat; their forehead is broad and open, their lips not pouting, and every feature of their face is regular and pleasant. Their physiognomy bears, in general, the marks of a character replete with frankness and amenity. Rochon compares them, with regard to their disposition and general character, to the savage, whose condition he absurdly extols, because, like the brute animal, he is destitute of all reflection on the past, and forethought with regard to the future. From the hair, complexion, and make of the natives of Madagascar, M. de Pagés conceived them to be descended from different races of men. Some who are short, with lank and smooth hair, of an olive complexion, have a strong resemblance to the Malay Indians, and do not seem to have originally sprung from the aborigines of the island. Others, tall and well-proportioned, with crisped locks, large and beautiful eyes, an easy carriage, and an open, unreserved countenance, appear to be the true posterity of the primitive inhabitants; their colour is nearly black, and differs but little from that of the natives on the Malabar coast. In their disposition they are lively and obliging, but wholly destitute of genius; vain, whimsical, and interested; dextrous in the use and application of their bodily faculties; but without the powers of combination, and in the general conduct of life, light, precipitate, and incapable of preserving a steady conduct, or of acquiring a decided character. With weak minds, they possess a considerable portion of wit and vivacity, and they blend a variety of good and bad qualities. They wear an apron at the girdle, and something of the same kind on the shoulders, with a bonnet constructed like an umbrella; the hair is combed into small tresses, and the beard is permitted to grow only on the chin. The men are little addicted to agriculture, but more inclined to look after their cattle, which roam in the woods. They construct war canoes, as well as canoes for their ordinary occupations. The latter are small, and navigated only with the oar; but the former, which are the property of the chief, are much larger, and have a sort of rigging. Some of them carry 100 men, and are in condition to sail round the island. The women are generally of the middle size, with expressive faces, and though not entitled to be classed with the handsome part of the sex, few of them are ugly. Round the waist they have a long apron, with a kind of under waistcoat, which barely covers the breasts. They frequently wear, by way of ornament, a large circular plate of silver; and round the neck, falling down upon the bosom, a number of small silver chains. Their hair appears in a multitude of little tresses, dangling over the forehead, or on the corner of the eye, or turned up in the form of a crescent. The women, besides cultivating fields of corn, rice, and other sorts of grain, are employed in planting trees and roots, particularly the cassava, batatas, and the banana or plantain. The leaves of the tree, named *rasia*, are made to supply them with thread; and with these materials, dyed of various colours, they manufacture a kind of cloth, which is woolly, and affords a very handsome article of dress. They prefer, how-

ever, the cotton stuffs imported by Europeans from the continent. Every family is provided with a loom, and carries on a manufacture equal to its own consumption. From the leaves of a tree, named *vacoua*, they procure materials for mats, bonnets, bags, and other useful articles. Their common food consists of rice, bananas, and dried fish; they consume little flesh meat or fresh fish; their drink is water, or the juice of the sugar cane, fermented with pimento and mustard. Their houses are small and awkwardly constructed. The walls are formed of bull-rushes, and the roof covered with plantain leaves. The chief part of the timber work consists of massy pieces of wood, the rest being bamboo, very rudely executed. The floor is laid with the pith of the palm, or some other tree, and is often raised far above the level of the ground, to avoid the exhalations of the soil, and also to guard them from the annoyance of serpents and insects during the rainy months. Although the natives have no regular form of worship, they nevertheless adore one supreme being, as the patron of justice and goodness, who will judge men after death, and reward or punish them according to the merit or demerit of their actions. The rite of circumcision is performed upon males between the 7th and 8th year of their age; and the day of circumcision is observed with festivity, and closed with the singular custom of firing from a musket the fore-skin of the patient. They believe also in a devil, or evil being; and upon this article is founded the craft of the Panfaret or Magician, who, being supposed to defeat or controul the machinations of the invisible enemy, practises a thousand tricks on the credulity of the multitude. Amulets of a species of wood, suspended round the neck, or preserved in a little bag, are supposed to secure the possessor against wounds and the disasters of war. A shrimp or toad, applied with words of incantation to the head of a person afflicted by disease, is expected to restore him to health. Exposing the sick in a hut of a certain elevation, open towards the east, from which is let fly an assemblage of party-coloured threads, is a sovereign remedy in the most desperate cases. Perfumes are introduced in abundance in all the arts and enchantments of the magicians. All these absurd observances seem to be the barbarous vestiges of religious notions, indistinctly transmitted to the people from their Asiatic neighbours. The rite of circumcision, the common use of perfumes, and a profound veneration for the quarter of the east, are evidently the remains of religious systems of the highest antiquity. But the most horrid part of their superstition remains still to be related. When an infant has the misfortune to drop into the world on a day esteemed unlucky, or of bad omen, by the Panfaret, he is exposed or suffered to die of want, or to be devoured by wild beasts. The natives are accustomed to hunt the whale along their coast; and when he is struck with the harpoon, they wait till his strength is nearly exhausted, and then lead him towards the shore. The women assemble on the beach, and vociferate songs of praise in honour of him who gave the first wound. The whale is then near the land, and surrounded by all the men in the village, when the public orator advances, and having pronounced a long oration on the pre-eminent qualities of the fish, the whale is cut up, and affords a rich repast to the company. When any subject of dispute occurs between the natives of Madagascar and the Europeans, or between Indians of different tribes, it is formally discussed in the "palaver," or council of the tribe; and the decision is the result of long deliberation.

Property in this island consists of cattle, grain, and slaves of the same nation with their master. Every person who has the misfortune to be made a prisoner of war, man, woman,

Or child, is reduced to the condition of slavery, and from that moment is regarded by his own kindred as an object of contempt. Their arms consist of a shield, and the "sagay," a kind of lance, which they throw with peculiar address. They are also tolerably well provided with muskets, purchased from the French; and they have also some swivel guns and cannon, obtained from the same quarter. The residence of the chief is within a fort or stockade, consisting of three rows of large trees, fixed in the ground so close as almost to exclude the light; and fastened together at the top by a cross beam. Their forts in general are mere simple palisades, constructed in the form of an oblong square; though some of them have bastions and galleries, with openings for the purpose of reconnoitring. On the eve of war, the women, children, and cattle, retreat to the woods, and there conceal themselves, waiting the issue of the campaign. The village is then occupied only by the men, who, previously to any act of hostility, sacrifice an ox. An Indian, of distinguished eloquence, harangues on the injustice of the enemy; and his countrymen, in the mean while, dip their sagays in the blood of the victim. Their operations in the field are of a very desultory description, consisting chiefly in teasing and harassing the enemy, or attempting to surprize him in the night. They seldom come to a regular engagement. The natives of Madagascar are susceptible of very violent enmities, and sometimes execute on their devoted objects the most deliberate cruelties. The customary use of presents is the same here as in India. It is the business of the inferior to make the first advance, as well as the first present; but he always receives another in return. The natives indulge in all the offices of hospitality; but not to the excess which some travellers have ascribed to them, who have said that it is customary for parents to prostitute their children to the embraces of strangers. This M. de Pages absolutely denies. He acknowledges, however, that chastity in the intercourse of the sexes is little regarded. The young ladies of Madagascar, habituated to intrigue, prompted by the political and pecuniary views of their parents, and captivated by the charm of some new ornament for their persons, cease to be reluctant to the wishes of their admirers. Married women are very little addicted to violate the nuptial engagement. When a woman happens to conceive by a foreigner, she recurs to various drugs, known to the natives, in order to procure abortion. In the language of Madagascar, which is by no means harsh or disagreeable to the ear, M. de Pages perceived some inflexions of voice which occur in that of the Philippine isles. It seems to be a compound of different languages, and contains many words borrowed from the Arabic and Portuguese.

The island of Madagascar is divided into a great number of tribes. Its population, says M. Rochon, may be reckoned at 4,000,000 inhabitants; but no precise calculation is possible; as the island is divided into distinct societies, each of which inhabits the canton which it likes best, and is governed by its own usages. A tribe consists of several villages, who all have a particular chief. This chief is sometimes elective, but more frequently hereditary. The land is never parcelled out, but belongs to those who take the trouble of cultivating it. These islanders have neither locks nor bolts, and live in a frugal manner. The French settlement of Fort Dauphin is in the south-east extremity of the island. For an account of it, see *FORT DAUPHIN*. The chiefs never go out without their gun, and a stick tipped with iron, ornamented at its end with a tuft of cow-hair. They wear a cap of red wool, by the colour of which they are distinguished from their subjects. In the province of Carcanossy, in which Fort Dauphin is situated, the terri-

ories are deemed to belong to the chiefs, who distribute them among their subjects for cultivation, for which they expect a small return. The people of this province are not quite ignorant of the art of writing. They have some historical books written in the Malegash language; but their men of letters, called "Ombiaffes," use the Arabic character. They have treatises on physic, geomancy, and judicial astrology. The most famous of them come from Mantatara, and profess geomancy and astrology in the public schools. The art of writing has doubtless been brought to this island by the Arabs, who conquered it between three and four centuries ago. The paper is manufactured in the valley of Amboul, and is wrought from the papyrus nilotica. The pens used by the islanders are made of bamboo. Their ink is prepared of a decoction in boiling water of the bark of a tree, called "Arandrato." The Arabic has made some progress in the north-west of Madagascar; and the Arabians have a staple on the river Bombetouque in the island, where they carry on commerce; and thus they have succeeded in introducing, with their language and learning among the natives, some traces of Mahometanism. The contiguity of Madagascar to the coast of Africa makes it natural to ascribe its population to that vast continent; and the different races of inhabitants are now so much confounded, as to render it a vain attempt to enumerate them. For an account of the *Kimoffes* of Madagascar, see that article. The north-eastern part of the island of Madagascar is the rich staple of the colonies of the isles of France and Bourbon. The most frequented harbours are "Foule Pointe," "St. Mary's," and the "bay of Antongil." In these three places the French have endeavoured to form colonies; but the incursions of pirates and the prevalence of the slave-trade have, according to Rochon's statement, by their consequences desolated the northern part of Madagascar. S. lat. 12° 30' to 25° 30'. E. long. 44° to 51°. Rochon's Voyage to Madagascar. De Pages' Travels round the World, vol. iii. See BENYOWSKY.

MADAGH, a town of Algiers, near the coast; 20 miles W.S.W. of Oran.

MADAH, a town of Persia, in the province of Segestan; 24 miles S. of Zareng.

MADALENA, or MAGDALENA, a majestic navigable river of South America, in New Grenada, reckoned the Danube of this province, which rises about 30 miles E. of Popayan, and after a northerly course of 100 miles, in which it is augmented by other rivers, runs into the Caribbean sea. The courses of this river, and also of the Cauca, are considerable streams, perhaps the issues of subterranean waters, from the vast cavity under the Table land, where the volcanoes often pour out destructive torrents of water and mud. N. lat. 11°. W. long. 74° 40'.—Also, a small island in the Pacific ocean, near the south coast of Chiloe. S. lat. 44° 15'.

MADALENA, *La*, a town of Canada, on the river St. Lawrence. N. lat. 46° 25'. W. long. 72° 25'.—Also, a small island near the coast of Sardinia. N. lat. 41° 15'. E. long. 9° 35'.

MADALENA, *La, Bay of*, a bay on the west coast of California. N. lat. 24° 53'. E. long. 247° 56'.

MADALENA, *St.*, a town of New Navarre; 150 miles S.W. of Casa Grande.

MADAMAT, in *Hindoo Mythology*, the son of Krishna and Rukmeni, and a name of Kama, the god of love; he having been incarnated in the person of Madamat, otherwise Madana, or Makadama. See KAMA.

MADAME ISLE, in *Geography*, forms the north-east side of the gut of Canfo, as you enter from the south-east, and

and is opposite to the eastern extremity of Nova Scotia. The north point of the island lies 14 miles S. of St. Peter's harbour, in Cape Breton island; on which island the isles de Madame are dependent.

MADAMPAR, a sea-port town of the island of Ceylon, on the west coast, at the mouth of a river.

MADAMUT, a town of Egypt, on the east side of the Nile; 20 miles S.S.W. of Kous.

MADAN, MARTIN, in *Biography*, an English divine of the established church, was born about the year 1726, and was brought up to the profession of the bar, which he quitted for the church, though without preferment. The chapel at the Lock-hospital was built chiefly by his exertions; and he officiated many years as the chaplain, without any emolument. He is chiefly known as an author by a work entitled, "Thelyphthora, or a Treatise on Female Ruin," in 3 vols. 8vo., published in 1781, which occasioned a long and very violent controversy. The author maintained the lawfulness, or even the duty of polygamy. Mr. Madan was a good classical scholar, and published a translation of Juvenal and Persius: he also wrote a treatise on "Capital Punishments." He died in 1790, having attained to much popularity as a preacher; and as a man, his moral character was unimpeachable.

MADAN'S POINT, in *Geography*, a cape on the north-east coast of the island of St. Christopher. N. lat. 17° 28'. W. long. 62° 38'.

MADANA, in *Hindoo Mythology*, a name of Kama, the Hindoo god of love, otherwise *Madamat*; which see.

MADAPASSA, in *Geography*, a town of Bengal; 60 miles S. of Dacca.

MADAPOUR, a town of Bengal; 10 miles S.E. of Rajamal.

MADARAVAN, a town of Fez, in the vicinity of iron-mines, not far from mount Atlas.

MADARGUNGE, a town of Bengal; 82 miles N.N.W. of Dacca.

MADAROSIS, from *μαδος*, *bald*, in *Surgery*, a loss of the eye-lashes.

MADBAH, in *Geography*, a town of Kemaoun; 23 miles S.E. of Kerigur.

MADBAN, a town of Hindoostan, in Bahar; 37 miles S.E. of Bettiah. N. lat. 26° 25'. E. long. 85° 21'.

MADBURY, a township of America, in Strafford county, New Hampshire, between Dover and Durham, about 10 miles N.W. of Portsmouth; incorporated in 1755, containing 544 inhabitants.

MADDAPOUR, a town of Bengal; 34 miles E. of Mauldah.

MADDEN, Dr. SAMUEL, in *Biography*, was born in Ireland about the year 1686, and educated at Dublin, where he resided the greater part of his life. In 1729 he was in England, and wrote a tragedy, entitled "Themistocles;" and was, as he says of himself, tempted to let it come out, by the offer of a noble study of books from the profits of it. In 1732 he published "Memoirs of the twentieth Century," a work which, for some reason not now known, was in a few days totally suppressed. In 1740 we find him in his native country, and setting apart the sum of one hundred pounds to be distributed in premiums for the encouragement of arts, manufactures and science; and the same sum he continued to bestow annually for the like purpose, so long as he lived. The good effects of these well-directed benefactions were not only felt in Ireland, but their influence was extended to the sister country, and, it is thought, gave rise to the "Society for the Encouragement of Arts, Manufactures, &c. in London," of which his grace the duke of

Norfolk is now the president. Dr. Madden obtained church preferment in Ireland, and he died in December 1765. He left behind him another tragedy, as a legacy to Mr. Sheridan. Biog. Dram.

MADDER, in *Agriculture*, the common name of a plant, sometimes cultivated in the field, as an ingredient in the dyeing of a scarlet colour. The sorts commonly cultivated for this use is, the *rubia tinctoria*, which is a plant of the thick fleshy tap-rooted kind.

It is stated by a late writer, that this plant "was formerly much more cultivated in particular districts in this country than it is at present, the importations from Holland having lessened the demands, and reduced the price of it, so much as to render its culture incapable of being conducted with profit to the farmer."

Soil.—The soils which are the most suited to the cultivation of this plant, according to the same writer, are those of the deep fertile sandy loams that are not retentive of moisture, and which have a considerable portion of vegetable matter in their composition. It may also be grown on the more light descriptions of soil that have sufficient depth, and which are in a proper state of fertility to admit of its being grown upon them.

Preparation, and Plants or Sets.—In the preparation of the land for the reception of this crop, "it will be necessary to plough it up deeply before the winter into high ridges, in order that it may be exposed to the action and influence of the frosts, and the atmosphere. Early in the spring these ridges should be well harrowed down by a heavy long-tined harrow, and then ploughed again in the contrary direction to a good depth. And when after this the land is not perfectly clean from weeds, or not rendered sufficiently fine and mellow, another ploughing and harrowing should be given. In the last operations the ground should always be left in as level and even a state as possible. It is then ready for the reception of the plants. The sets or plants may then be obtained either by sowing the seed upon a bed of earth which is rich, and made perfectly fine by digging and raking in the spring, and then lightly covered in, or from offsets or suckers from the old plants. In the first method, on the plants appearing they should be made perfectly clean by weeding, and be set out to the distance of three inches in the beds by the hoe. In this way, by keeping the ground quite clean and well stirred about the plants, they will be ready to set out in the second autumn, though it will mostly be better to defer the business till the spring, in this climate, if the sets can be procured, as the plants seldom ripen their seed perfectly, or afford it in a state to vegetate well. It requires about twenty thousand plants for setting an acre of land. The most suitable time of taking the sets is shewn by the plants having attained the height of ten or twelve inches from the ground, and the suckers having thrown out fibrous roots at their bottoms. This may be seen by drawing up a few of the plants, and usually about the latter end of May or beginning of June." Besides "it is necessary that the sets have formed root-fibres at the bottoms, before they are removed, as where that is not the case, they never succeed well."

The land being prepared in the manner directed above, and the plants thus provided, "a sufficient number of labourers are to be provided, that the work may be performed as expeditiously as possible. In taking off the sets, much care is necessary not to injure them. Some perform it by means of a dibble with a flat edge, and which is shod with iron; this tool, on being thrust into the ground on the side of the shoots, divides and separates them by depressing the handle without hurting the fine fibrous roots. The number of plants

MADDER.

plants that can be set in a short space of time should only be taken up at once. They should be prepared by having about a third of their top parts cut off. A sort of thin batter should likewise be made, by mixing good vegetable mould and water well together, into which the roots of the sets should be dipped before they are placed into the earth, as by this means the necessity of watering the plants afterwards is prevented. This work is executed by a person before the planting commences. Two others are employed afterwards in distributing the plants so as to be convenient for putting them into the ground."

There are different methods employed in setting the plants; in some cases they are put in the furrow by means of the plough, while in others they are set in beds by a dibble. The former is probably the better method, and as being the most expeditious, is best adapted to the culture of the plant on an extensive scale. In this the planter begins by drawing a straight furrow on one side of the plantation to a good depth; a row of plants is then laid in it by a person for the purpose, at the distance of five, six, or more inches from each other, according to the circumstances of the land, in such a manner as to lean off from the plough; another furrow is then formed, by the mould of which they are covered. In this manner the work proceeds until the whole is finished.

In the other method, it is observed, the sets, after the land has been formed into beds, five feet in breadth, with two feet between each for intervals, are put in by means of a line and a dibble, beginning at the distance of six inches from the out-sides, and setting a row of plants at suitable distances from each other, as just mentioned; then removing the line two feet farther on them, and putting in another row; after which it is again removed two feet, and a third row of plants set in, which finishes the bed; the work proceeding in this manner till the whole of the plantation is completed. In this way each bed contains three rows of plants, at two feet distance each, three feet being left between the rows on the different beds."

But "in Holland, where the culture of this root is extensive, their method is, it is observed, a little different from the above. The plants, after being taken from the older plantations about the month of May, are immediately set in rows at the distance of three or four inches from plant to plant, and about fifteen inches from row to row, the beds being ten or twelve feet in width, with intervals of only about two feet."

It is suggested that, "as in whatever manner the plants are set, some of them, even in the most favourable seasons, are liable to die soon after the work has been performed, it is necessary, in the course of a fortnight or three weeks, to look over the ground and put fresh vigorous plants in the places where the others have been destroyed. By this means the plantations may be rendered more perfect and productive."

But whatever method of planting may be practised, it is of the greatest importance to the success of the crop, "that it be kept perfectly clean from weeds, and that the mould be occasionally stirred about the roots of the plants." The first of these is accomplished, according to the survey of Kent, by means of hand-weeding and hoeing during the summer season, and the latter either by the use of a hand-hoc, or a light plough; this last is the most easy and expeditious. In this manner, or by digging the intervals of the rows, the mould is also laid up to the plants once each year after the stems have been removed in the autumn season. Where the bed practice is followed, they are sometimes earthed up in the autumn after the stems have been cut down, by paring the intervals somewhat in the manner of those of the asparagus kind. This method is, however, in general

too expensive and troublesome where the crops are cultivated on an extensive scale.

According to Mr. Young, the best way of performing this culture is "to use the shim, not for turning a ridge against the rows, as the plants will yet be too weak for that operation, but merely to loosen the earth of the intervals, thereby to kill the weeds, and prepare the soil for being thrown up against the rows by a succeeding operation. Hand-hoeing and weeding should depend on the number of the weeds that arise among the plants. Let the cultivator of madder, through the whole process of the crop, remember, says he, that he must be to the full as accurate as a gardener; his soil must be rendered little inferior to a dung-hill; all weeds must be forever eradicated; not one must injure the plants; his land must always be kept perfectly loose and well pulverized; for a crop that depends merely on the quantity of the roots, can never thrive to profit in land that is bound or in an adhesive state."

Whatever practice is adopted, "the crops are to be managed in this manner until the third autumn after planting, when the plants will be in a state to be taken up; this is known by their stalks beginning to wither, and is generally about October. This business is performed either by trenching the land over with a spade, or by means of the plough. The first is the more certain, though much less expeditious method. In executing it, the workmen dig along the rows to the depth of about two feet, breaking and reducing every spit of earth as perfectly as possible, each being attended by two persons, who pick out the roots of the madder. But when the planting has been done in narrow-beds, it is sometimes the practice to take the roots up by turning the earth into the intervals by a *spud*, or broad three-tined fork. In this way it is supposed that the roots are taken up more perfectly, and with less danger of being injured. But the most ready method is by means of the plough, which after having the earth-board and coulter removed, is passed along each side of the rows, so as to fully loosen the mould; persons being employed to pick out the roots, loosening such parts of the earth as may have escaped the action of the plough by their spades." And "when the roots have been taken up, they should be exposed some time to the air, in order that they may be rendered so dry as to be cleared from dirt. They are then to be conveyed to a kiln, such as is employed for the purpose of drying malt, or hops, when they are to be brought into such a state of dryness as to be perfectly brittle. This is to prevent the danger of their being injured by becoming mouldy, or from running into a state of fermentation; but much caution is necessary in conducting the process. After this they are packed up in bags, in order to be disposed of to the dyer, who reduces them into a powder by a mill before they are made use of as a colouring ingredient." Mr. Young, however, observes, that he is "informed, that at present (1803) the largest quantity of madder used in our manufactures, is used without being powdered as formerly, and that it is saleable with common drying, without stove-work; but that, that common degree is open to much uncertainty, so that the preceding remarks are not done away. The price of 4*l.* per hundred weight, marks a considerable defecation in his opinion."

It is hinted, that in order to judge of this root, the best is that which, on being broken in two, has a brightish red or purplish appearance, without any yellow cast being exhibited.

It is stated, "in order to collect the seed of the madder plant, it is necessary to let the plants remain in the field till the seed is almost wholly ripe, which is generally in the month of September. The heads are then to be separated from

from the stems, and exposed in a cloth in the sun, till the seed can be easily forced out by slightly beating them. It is then to be rendered perfectly clean, and afterwards placed in a sunny situation, until it become quite dry; for if the least dampness remain, it will grow mouldy, and its vegetative power be either greatly impaired or wholly destroyed. When thus properly dried, it should be put in small bags, and hung up to the ceiling of a room where a fire is constantly kept."

The produce from the root of this plant is different, according to the difference of the soil; but mostly from ten to fifteen or twenty hundred weight, where they are suitable to its cultivation.

It seems not improbable, a late writer says, "that the cultivation of madder might be rendered a profitable article of field-husbandry in different districts, if the importation of the root from Holland was prohibited; as the event of different trials has shewn that full crops of good madder are capable of being raised." And it is supposed by the intelligent writer of the Survey of Kent, "that if the price was never lower than 3*l.* the hundred weight, it might be grown not only with profit by the farmer, but without injury to the consumer." As it is supposed, "from the high degree of culture which land under this sort of crop must necessarily undergo, and its not being so much exhausted as in many other cases, that it must be an excellent preparation for wheat, or any other crop that requires a clean and fine pulverized condition of the mould or soil."

But the author of the Farmer's Calendar "recommends the young farmer to remember that the culture of these plants, applicable only to the use of manufactures, and which are also largely imported from abroad, is rarely advisable. He was a madder planter once, and lost by every acre he planted. A man may plant at the moment of a high price, and take up his crop three years after at a low one. All such speculations are too hazardous; nor was there even a fair open competition among the purchasers. Those who have cultivated madder with the success boasted by the writers of husbandry, should not hold these observations in contempt. There appears to him almost as much use in mentioning trials that were unsuccessful, as in those that are ever so profitable; for it is certainly of as much consequence to tell one man that his soil *will not do* for madder, as to assure another that his *will do*. Instead of an acre or two, he might possibly have launched (like many others) into ten or fifteen acres; in which case, the loss would have been no trifle. And it is surely highly incumbent on every one to make known to the world such of his experience as will probably be of any use to it. Bad success of several persons in a culture is too apt to prejudice others in general against it. However irrational, still it is so; and it ought to be a caution not to recommend any thing in general, under the extravagant notion, that because an article of culture is profitable on one soil, it must be the same on very different ones. But the grand obstacle to the culture of madder is the difficulty of sale; for while a man has not a fair market for his unmanufactured madder, none can with any prudence engage in it, unless on so large a scale as to admit the whole apparatus of reducing it to such a state as to be absolutely a marketable commodity. In answer to this it may be said, that madder really dry is a *marketable commodity*. But this matters not, if the purchaser has it in his power to be a knave: he has a pretence, a screen always at hand that will cloak the greatest knavery, and to a degree known in no other branch of agriculture. Among the gentlemen of trade who have a mutual understanding and confidence, such objections appear trivial; but to the culti-

vator at a distance from the market, it is a different affair. He writes to a madder-merchant to know the price. The answer is, *4*l.* an hundred weight*. Up he sends his madder, and instead of *4*l.** he receives but *3*l.**, not from a variation in price, but in weight. It may be said, that the correspondent in London may be right. Very true; but will the countryman believe it? He thinks himself right, and has no other proof that he is not so but the interested assertion of the man who buys it. Is it not evident that, in such a case, the cultivator will be disgusted, and throw aside a business in which he knows neither the market-weight nor the market-price? If encouragement is designed to this culture from any quarter, it should not be exclusive of this circumstance. Manufactures should be erected and established, in which the madder could be prepared for any one, at so much an hundred weight, and that by persons not the least concerned in purchasing. Then the cultivator would have a commodity in his hands, which he could sell in as simple and fair a way as any other. If nothing of this sort can be effected, all encouragement should be for such a number of acres (and no less) as will answer the expence of a private manufacture; which would prevent persons being rashly drawn in, by premiums apparently considerable, to cultivate a root which, when raised, is in its sale absolutely at the mercy of the purchaser."

Kilns are often necessary in the culture of this root; but for small crops, a common oven may serve, though it is very tedious, and would require large ovens to supply the place of kilns. However, to save the expence of building such kilns, a place may be made over the roof of the oven, to put the roots in, that they may begin to dry. Where much madder is grown, it is, notwithstanding, absolutely necessary to have a kiln proportioned to the quantity that is to be dried. These may be made of different forms, being attentive that it may contain a large quantity of roots; that it be worked with ease, and the smallest proportion of fuel; and that it may be so contrived as to retain an equal moderate heat.

Those made use of in the Low Countries differ very little from that used here in drying malt. There is a large furnace, in which a great fire is made: this furnace is made under an arch; the hot air and smoke pass through a funnel over the furnace, and spread themselves in a space in form of an inverted pyramid, the bottom of which is covered with a perforated floor, on which the madder-roots are spread. See KILN.

And where the manufacture of the article is carried on, a mill for the purpose of pulverizing the dried madder is likewise necessary. See MILL.

Expences of Culture per Acre.—This is on land worth forty shillings per acre, in the digging mode, and before the great rise in the price of farm labour.

	£	s.	d.
Rent for three years	6	0	0
Digging ditto at two-pence per perch	1	6	8
Dividing ditto into beds, two men one day, at one shilling each	0	2	0
Raking ditto, two men one day, at one shilling each	0	2	0

In this estimate, which is much below the present price, nothing is allowed for plants; as, though expensive at first, when once done, a supply from the plantation will constantly be had for a long time.

MADDER, in *Botany and Gardening*. See RUBIA.

MADDER, in *Law*. See LARCENY.

MADDER, in the *Materia Medica*. The roots of madder were employed by the Greek writers with the same medicinal intentions for which they are recommended by most modern writers on the materia medica. Madder differs from some other substances used in dyeing, by its property of tinging with a florid red colour, not only the milk, urine, &c. but the bones of those animals which have fed upon it. This circumstance was first noticed by Antonius Mizaldus, (*Memorab. ut. ac jucunda Cent. 7. Aph. 91. Lutet. 1566.*) but not known in England till Mr. Belchier published an account of a pig and a cock, whose bones became red by eating madder mixed with their food. (*Phil. Trans. vol. xxxix. vol. xli.*) Since that time various experiments have been made, by M. Hamel du Monceau and others, from which it appears that the colouring matter of madder affects the bones in a very short time, and that the most solid or hardest part of the bones first receives the red colour, which gradually extends, *ab externo*, through the whole osseous substance; while the animal continues to take the madder; and if the root be alternately intermitted and employed for a sufficient length of time, and at proper intervals, the bones are found to be coloured in a correspondent number of concentric circles. *Mem. de l'Acad. des Scienc. 1739. Med. Ess. Edinb. abr. vol. ii.*

According to Lewis (*Mat. Med.*), the roots of madder have a bitterish, somewhat austere taste, and a slight smell not of the agreeable kind. They impart to water a dark red tincture, to rectified spirit and to distilled oils a bright red: both the watery and spirituous tinctures taste strongly of the madder.

By medical writers, madder has been considered as a deobstruent, detergent, and diuretic, and is chiefly used in the jaundice, dropsy, and other diseases, supposed to proceed from visceral obstructions, particularly those of the liver and kidneys; and some modern authors have recommended it as an emmenagogue (*Home's Clin. Exp.*), and in rickety affections. (*Levret sur les Accouchemens.*) With regard to its diuretic quality, for which there are several respectable authorities, Dr. Cullen asserts, that in many trials, both for this and other purposes, such an effect is not constant, as it never occurred to him. As a remedy for

the jaundice, it has the authority of Sydenham, and was formerly an ingredient in the icteric decoction, which the college of Edinburgh directed to be prepared by boiling an ounce of madder, the same quantity of turmeric, and the same quantity of the roots and leaves of celandine, in three pints of water to a quart; to which, when strained and cooled, the juice of 200 millepedes are added; and a quarter of a pint of this liquor was ordered to be taken twice a day, or oftener. But as this decoction seemed to be more adapted to the "fæces albidæ," than to the disease itself, it was expunged from the Pharmacopeia. That some French writers should prescribe madder in a rickety state of the bones, appears a little surprising, says Dr. Woodville, as the brute animals to which it was given, especially the younger, suffered considerable emaciation and prostration of strength from its effects. Its virtues, as an emmenagogue, rest principally on the authority of Dr. Home, who gave from a scruple to half a dram of the powder, or two ounces of the decoction, three or four times a day. But this medicine failed with Dr. Cullen, who also says, (*Mat. Med. vol. ii.*) "I know of other practitioners in this country, who, after several ineffectual trials made with it, have now entirely deserted its use." *Woodv. Med. Bot.*

MADDER, *Rubia Tinctorum*, in the *Arts and Manufactures*, grows wild in many parts of the Levant, as well as in the south of Europe, and has been very largely cultivated in Holland, particularly in Zealand, and also in the northern parts of Europe, for the use of the dyers and calico printers. (*See DYEING.*) The method of cultivating it in Holland is this: in autumn they new plough the land, where the madder is to be planted, if it is strong and heavy, laying it up in high ridges, that it may be mellowed by the winter's frosts. In March they plough it again, working it very deep, and laying it in ridges at eighteen inches asunder, and about a foot deep. Then, in the beginning of April, when the madder begins to shoot out of the ground, they open the earth about the old roots, and take off all the side shoots, which extend themselves horizontally just under the surface of the ground, preserving as much of the root as may be with them. These they plant immediately on the tops of the new ridges, at about a foot distance from each other; and this they usually do in showery weather, when the plants immediately take root and require no more water. In these ridges they let the plants remain two seasons, keeping them clear of weeds; and at Michaelmas time, when the leaves are fallen off, they take up the roots, and dry them for the market. See RUBIA.

The madder-plant grows to about three feet in height, but it is the long-spreading fibrous root that is used in dyeing. The madder of the Levant, called "Lizari," or "Azala," has a somewhat higher and finer colour than that of the Dutch; but that of Holland is more carefully prepared. The Dutch method is as follows: the roots, as soon as they are gathered, are put under a shed, or in a granary, or other sheltered place, and there remain, exposed to a current of air, for ten or twelve days, till they are quite pliable, and till no juice can be pressed out by squeezing them. They are then farther dried, either in a common oven of slack heat, if the quantity be small, or in large stoved rooms, constructed for this purpose, and heated with turf, a large opening being left for the escape of all the internal vapours. This process requires particular attention and management. When the roots are quite hard and brittle, they are laid on a threshing-floor, and beaten with a flail, in order to separate the dirt and outer thin skin; they are afterwards ground in a mill, and the powder, being sifted and sorted, is carefully

M A D D E R.

fully packed in large barrels: it is thus exported, and in this state used by the dyers. For the method of cultivating and preparing madder in England, see the article RUBIA. The method practised in Turkey and Persia for preparing the madder used in the beautiful Adrianople red, is stated by an eye-witness, cited in Aikin's Dictionary, to be as follows: For every 100lb. weight of the fresh root, a steeping liquor is prepared of 2lbs. of bran, and 1lb. of honey and alum, in four gallons of water. The roots, having been previously washed clean, are soaked in this liquor for two or three days, and then dried, first under cover, and lastly in the sun. They are afterwards ground and sifted, the powder last produced in the mill being of the best quality.

The powder of madder should not be dry and harsh, but feel somewhat greasy, and adhere together under the fingers. Madder-root consists of three parts, *viz.* the skin or cuticle which is rubbed off under the flail, and is of no use; a thicker bark or cortical part, and within this a woody portion. These two latter parts are of a high red, and both are intermixed with many yellowish particles, which injure the red colour, but cannot be separated in grinding the root. When the colour is extracted in the dyeing vat, the red part is less soluble in water than the yellow, and is not so readily extracted; and, therefore, the beauty of the red colour is deteriorated by long boiling, and by using too large a quantity of the root. In the state of madder, when used by the dyers, it is an orange brown powder, liable to become damp, and to be spoiled in a moist place. As to the chemical properties of madder, we shall detail the following experiments by Mr. Wali, from Berthollet Elem. de Teinture, vol. ii. Zealand madder of the best quality, was of an orange-brown colour, and in moderately fine powder. This powder, with water, gave an orange-red infusion, by maceration with or without heat, but in the latter case the colour was finer. By slow evaporation of the infusion, or decoction in a shallow vessel, a pellicle is gradually formed, and sinks to the bottom, and is successively replaced by others. The extract, when nearly dry, is of a dingy brown, and is only in part again soluble in water. Alum added to the infusion gives a precipitate of a very deep brown-red, and the supernatant liquor assumes a brownish-yellow tinge. If the alkaline carbonats be added to this liquor, they give a blood-red lake, miscible with oils, but very inferior in beauty to the cochineal lake. With an excess of alkali, the precipitate is re-dissolved, and the liquor becomes red. The colour given by soda is not so fine as that by pot-ash. Lime precipitates a brown-red lake, having no beauty. The acids added to all infusions of madder turn it yellow, but form no precipitate. The natural colour is again restored by alkalis. Carbonat of magnesia, added to the water in which madder is infused, turns it of a clear blood red colour, which, when spread upon paper, becomes yellow by the sun's rays. The following effects are produced by different metallic solutions: acetate of lead, added to the aqueous infusion of madder, gives a brownish-red precipitate; nitrat of mercury a purple-brown; sulphat of iron a beautiful clear brown; and sulphat of manganese also a purplish-brown. The solutions of tin, as Berthollet observes, produce a lake void of brilliancy and beauty, owing, as he conjectures, to the precipitation of the yellow as well as the red particles of madder, so that this metal, which serves to heighten the beauty of cochineal, can hardly be used with any advantage for madder. Sir Henry Englefield has invented a method of extracting the red of madder of lakes, for which he obtained the gold medal from the Society of Arts. (See Transf. of the Society, vol. ii.) His method is founded on the disco-

very that the red colouring part is scarcely soluble in cold water, but in the usual method of extraction is chiefly suspended by means of the mucilage of the root. His principal process is as follows: Inclose two ounces (troy weight) of the finest Dutch madder, known in commerce by the name of "crop madder," in a bag capable of containing three or four times that quantity, made of strong and fine calico. Put it into a large marble mortar, and pour on it a pint of soft river water, pressing the bag in every direction, and rubbing it as much as possible without danger of bursting; the water will soon become quite opaque, and loaded with colouring matter. Pour off the water, and add another fresh pint of water, triturating it with the madder as before; and repeat the operation, till the water, the last added, comes away but slightly tinged. About five pints will be required to exhaust the colour, after which the root, if taken out dried, will be found to have lost $\frac{1}{8}$ ths of its weight, and also its peculiar smell; and the colour will be a light nankeen or cinnamon. The water loaded with the colouring matter must then be put into an earthen or well-tinned copper vessel (not iron) and heated till it just boils. Then pour it into a large basin, and add an ounce of alum dissolved in a pint of hot soft water, carefully stirring the mixture. Afterwards add about 1½oz. of a saturated solution of carbonat of potash, which will immediately excite an effervescence, and a subsequent precipitation of a coloured lake. When it has stood till cold the lake is to be collected, well washed with repeated quantities of warm water, and gently dried. It will then be found to weigh about half an ounce, or a fourth part of the madder employed. This madder lake, which is very beautiful, is found by analysis to consist of more than 40 per cent. of alumine, the remainder is the colouring matter of the madder. If the alum solution and the madder infusion, without the alkali, be suffered to stand for a while, a dull red lake will equally precipitate, and the clear liquor will afterwards yield a beautiful ooze-red lake by alkali, but wanting a sufficient body of colour. A lake equally good with the first mentioned, but of a lighter colour, will be afforded by previously allowing the madder and cold water to stand for a few days in a moderately warm place, by which a slight fermentation will be induced, and a portion of the mucilage of the root destroyed. The process is then to be continued as before. The same ingenious experiments also succeeded very perfectly in obtaining a still more beautiful and equally durable lake, from the fresh madder-root imported from Holland, packed up in moss. Aikin's Dict.

Wool, previously boiled in a solution of alum and tartar, receives from a hot decoction of madder and tartar, a very durable, but not a very beautiful red colour. M. Margraaf (Berlin Mem. 1771) shews how a very durable lake, of a fine red colour, fit for the purposes of painting, may be obtained from madder. The process is as follows: take two ounces of the purest Roman alum, and dissolve it in three (French) quarts of distilled water that has boiled, and in a clean glazed pot. Set the pot on the fire, and when the water begins to boil, withdraw it, and add to it two ounces of the best Dutch madder. Boil the mixture once or twice, then remove it from the fire, and filtrate it through a double filtre of paper not coloured. Let the filtrated liquor stand for a night to settle; and pour off the clear liquor into the glazed pot, well cleaned. Make the liquor hot, and add to it gradually a clear solution of salt of tartar in water, till all the madder is precipitated; filtrate the mixture, and upon the red precipitate which remains upon the filtre, pour boiling distilled water, till the water no longer acquires a saline taste; the

red lake is then to be gently dried. The colour of this precipitate is deep; but if two parts of madder be used to one part of alum, the colour will be still deeper: one part of madder, and four parts of alum, produce a beautiful rose-colour.

MADDOX, ISAAC, in *Biography*, who arrived at the highest honours of the church, was descended from parents of rather mean rank in London. Of those parents he was deprived while very young, and he was placed in a charity-school, where he imbibed a taste for useful knowledge. An attempt was made to put him apprentice to a pastry-cook, but his love of reading, and his desire after learning, seem to have unfitted him for that employment, and he was, by the interest of his friends, allowed to pursue his studies at one of the Scotch universities. It has been said, but the fact seems at least doubtful, that he became a preacher among the dissenters for a short time. It is certain that he refused to take orders in the church of Scotland, and, probably by his talents, obtained the patronage of bishop Gibson. He was, by the interest of the learned prelate, admitted of Queen's college, Cambridge, and soon after received episcopal ordination. He was first appointed curate of St. Bride's, and then domestic chaplain to Dr. Waddington, bishop of Chichester, whose niece he married, and was afterwards promoted to the rectory of St. Vedast, Foster-lane, London. In the year 1729 he was appointed clerk of the closet to queen Caroline, about which time he was created a doctor by a diploma from Lambeth. In 1733, he was made dean of Wells, and in the same year he published "A Vindication of the Government, Doctrine, and Worship of the Church of England, established in the Reign of Queen Elizabeth." The work was a sort of answer to, or attack on, Neal's History of the Puritans. This defence of the church, together with his interest by marriage and otherwise, paved the way for his preferment, and he was in 1736 consecrated bishop of St. Asaph, from which see he was translated to that of St. Asaph in 1743, and from thence to Worcester. Excepting the volume already referred to, the bishop published only fourteen single sermons, preached on public occasions, between the years 1734 and 1752. The bishop died in 1759, about the age of sixty-two. As a prelate, he discharged the duties of his station with fidelity and much diligence: in the government of the clergy he acted the part of a prudent and affectionate father. He was always liberal, and in many instances munificent: during his life, he gave two hundred pounds a-year towards the augmentation of the smaller benefices of his diocese. He was a zealous encourager of public and benevolent institutions. To the London hospitals he was a great benefactor, and was among the first promoters of the Worcester infirmary. In his manners he was distinguished for cheerfulness, affability, and good nature, and was at all times above the false pride of concealing his humble origin. At one of his entertainments he pressed the company to taste his pastry, saying he believed it was good, but he could assure them that it was not of his own manufacture. Gen. Biog.

MADE STREAMS, in *Agriculture*, such as are formed by art, as in the case of irrigation, &c.

MADEE, in *Geography*, a town of Hindoostan, in Telingana; 38 miles of Warangole.

MADEIRA, a well-known island in the Atlantic, of which Funchal, situated near the eastern extremity of the south coast, is the capital and bishop's see. The first sight of the island is peculiarly magnificent to those who have never travelled beyond the British channel. The entrance to the bay affords a most beautiful prospect of the city of Funchal and of the surrounding country, which from every part of the coast rises so steep as to bring very distant objects into a fore-ground, like a Chinese landscape. As high as the temperature will admit the hills are clothed with vines, in the midst of which a white mansion, at agreeable distances, is discovered, and on the highest habitable part of the hill is an elegant chapel, dedicated to Nossa Senhora de Monte. To the left of this is a beautiful country seat, with a fine hanging wood, erected by the late consul, Mr. Ch. Murray, and since purchased by a Portuguese nobleman. Above this the mountain is covered with woods or verdure, as high as the sight can distinguish, and indeed in every part, excepting those columnar peaks, the soil of which has been washed away by the violent rains to which those latitudes, and particularly such elevated parts, are liable. The whole island is said to be about 40 miles in length, and 11 in its greatest breadth. The altitude of Pico Ruivo, its highest land, taken by the barometer and thermometer according to M. de la Luc, is estimated at 5068½ London feet. To Mr. Johnson, called by the Portuguese the accomplished Englishman, we are indebted for an accurate map of Madeira, and many other very valuable remarks. Though partner in a considerable mercantile house, he was a well-educated man, and always turned his acquirements to the benefit of others. His observations, confirmed, we believe, by the quadrant, estimated the peak somewhat higher. This is, however, nearly an English mile, elevated on a surface of about five miles on each side, which is enough to give an idea of the prodigious steepness of every part of the island. From Pico Ruivo, situated nearly at the eastern extremity of the mountainous part, there is a kind of table land, running westward for more than twenty miles, in some parts extremely narrow, and from its elevated situation so tempestuous during the winter, that no habitations are found in its whole extent. This is called Paulo da Serra, and is said to be level ground, a comparative term in an island, the surface of which is so universally uneven. The following account of the geology of Madeira is offered as the most recent, though in many respects imperfect, from the short stay of the honourable H. G. Bennet, to whom we are indebted for it.

"It consists," says that gentleman, "of a succession of lofty hills rising rapidly from the sea, particularly on the eastern and northern extremities. The summits of many of these ranges present the appearance of what has been called a table land; yet occasionally the forms are conical, and surmounted by a peak, which in some instances I found to be of columnar basalt. Deep ravines or vallies descend from the hills or *ferras* (so called from the interfections the eye meets with in viewing from below the different chains of mountains) to the sea, and in the hollow of most of them flows a small river, which in general is rapid and shallow. The soil of the island is clay on the surface, and large masses of it as hard as brick are found underneath. Though there are not at present any existing volcanoes in the island, yet the remains of two craters are to be seen, one on the eastern, the other on the western side, the largest being about a Portuguese league, or four English miles, in circumference. Every thing around wears marks of having

MADEIRA.

suffered the action of fire; yet I was unable to discover any deposit of sulphur, and was told that none had hitherto been found in the island.

"The varieties of strata, which I shall term generally lava, are not numerous. I myself saw but four, and I was informed there were no more to be met with. Three of them were invariably alternating in the same order. The first or lowest lava is of a compact species, containing few, if any, extraneous substances, is of a blue colour, and of a remarkably fine grain. Upon that, the second, which is a red earthy friable lava, rests; sometimes separated by beds of clay mixed with pumice, and layers of black ashes and pumice. This red lava contains minute pieces of olivine; sometimes it assumes a prismatic form, and in one place was of a moderate degree of hardness: the principal springs of water in the island issue from this stratum. On the top is the third, a greyish lava, generally compact, though at times near the surface very cellular, and containing much olivine. This lava takes principally the prismatic form of basalt. I have seen it in the most perfect prisms from 30 to 40 feet or more in height, the surface being covered with scoria, ash, and pumice. These masses of lava contain more or less of what I consider to be olivine, occasionally carbonate of lime and zeolite, which last assumes either a crystallized or globular form, or is diffused in a thin coating between the different layers.

"The fourth species of lava is of a coarse grain, is used for the making of walls, and the commonest and poorest houses are built of it, the blue and grey lavas being used for the copings, &c. It works easier than the two other kinds above mentioned, is more friable and soft, and its colour is a mixture of brown and red. I observed it in a stratum by itself, and it did not seem to have any connection with the other three kinds.

"These are the principal stratified lavas that the island affords; but in the beds of the rivers, particularly in that which flows in the valley of the Corral, several varieties occur in isolated masses, containing olivine and zeolite in greater or less quantity, and exhibiting detached portions of strata, similar to those that are found in the Fossa Grande on the side of Vefuvi is.

"I also examined the coast to the westward of the town of Funchal. From the beach before the town to Illhoo Castle, and beyond it to the land called the *Punta de la Cruz*, the general character of the coast is as follows: The red stone is the apparent base upon which rests a bed of grey prismatic lava, the stratum being sometimes from 40 to 100 feet in depth. At times this grey lava rests upon a deep bed of ashes and pumice, agglutinated together like the *peperino* and *puzzolano* in the vicinity of Naples. The scoria at the surface is remarkably thick, and all the upper parts of the lava appear to be cellular. The general dip of the lava on the coast near Funchal is to the north, but near the fort of Illhoo it forms with a mass of pumice that is intersected with slight veins of carbonate of lime and zeolite, a rapid angle or curve of declination to the east. To the westward of the fort, the lava is not found for a little distance, and there is nothing but deep beds of pumice and the agglutinated mass above mentioned. These beds of pumice are of various thickness, the deepest appearing to be about four feet, and alternating with that stratum which I have called *peperino*. In different cavities of the pumice bed, there are large deposits of black ashes. Towards the extremity of the strata the red stone appears on the surface in a more solid state, and lies in prismatic masses, the prisms being small, and not exceeding a few inches in diameter. Their substance is brittle, and crumbles with ease. This stratum of red lava

is of a short continuance. Passing a small brook, it dips rapidly to the westward, and in its place the grey lava is found in a confused though sometimes prismatic form, and rises from the beach, while the red lava still runs along the surface to the height of near 100 feet, the top being covered with a thick scoria.

"There is also in the vicinity of Funchal, to the eastward of the town, a fall of water, which, independent of the romantic beauty of the situation, merits being visited on account of the exposure of the two strata of lava in their relative position. The hills are composed wholly of lava, sometimes of a confused, sometimes of a prismatic formation, the red and grey lavas being visible on both sides of the valley. Near the head of it, a short distance from the cascade, the red stratum is at the bottom, and about 60 feet higher it re-appears, and again, about 200 feet higher, alternating with the grey lava. The upper red lava dips rapidly to the south, and the strata are disposed in the following manner:

"The rock, down which the cascade falls, is also intersected with a red stratum of about three feet wide, that traverses it, and dips to the westward, and is broken off by a broad dyke of grey lava. It appears about 30 feet higher, and dips again to the westward. The substance of the red rock in this place is hard, and it breaks into a columnar form, being by far the most compact of the red strata I met with in the island. I saw this red lava also in the island of Teneriffe, to the eastward of Santa Cruz, as well as in the neighbourhood of Orotava."

From the sides of Pico Ruivo arise three principal rivers, which traverse the island in different directions. Besides these are two very considerable fountains on the table land, and various other tributary streams. This command of water at such a height is a most munificent blessing of providence in a country usually free from rain for more than six months of the year, the steepness of which renders the rivers in their natural forms little better than cataracts. By diverting the water to the sides of the mountains by regulations long established among the colonists, tracts of land are fertilized, which must otherwise remain for ever unproductive, or exhibit only trees and prickly pears (*cactus mamillaris*) whose roots would often become bare by the torrents of the rainy seasons.

The following is the popular tradition of the discovery of Madeira. One Machin, an Englishman of obscure birth, had fallen in love with a young damsel, called Anne d'Arset, of exquisite beauty, and of a noble family, which disdain- ing so low an alliance, though Machin had gained her affections, obtained a warrant from the king to keep him in prison, until the lady was persuaded to marry a nobleman, who took her immediately to his seat near Bristol. Machin, being some time afterwards released, found means to convey the lady on board a vessel provided to carry them to France.

MADEIRA.

France. When they were far at sea, a storm arose, and they were tossed for thirteen days on the waves out of sight of land. At length they perceived something that appeared like an island, overgrown with wood. The ship soon came to anchor, and Machin and the lady, with a few attendants, went on shore. In the course of the night a tempest drove the vessel from her anchor, and carried her to the coast of Barbary, where she was wrecked, and the seamen made captives by the Moors. The lady, affected by this disaster, died in a short time, and Machin, through grief, soon followed her. Their attendants, rendered desperate by the loss of their conductor, quitted the island, and betaking themselves to their open boat, put out to sea, without knowing what course to steer. After a series of adventures, they fell in with a Spaniard, who, delighted with their story, communicated it to Gonçalves Zargo, sent out by the king of Portugal on a voyage of discovery, and prevailed upon him to sail in search of the island, who in a little time found it.

This story, though unnoticed by De Barros, the Livy of the Portuguese, is not only authenticated by a contemporary historian, but, after a very minute inquiry of the late Rev. Mr. Roberts, we are assured, stands on as fair a foundation as any other historical fact. The gentleman we allude to, being a clergyman of the Roman Catholic persuasion, and a native of Oporto, had the most favourable opportunities of ascertaining the fact, which diligence, knowledge of the languages, and access to every library, could afford him, and expressed his firm persuasion that the legend of Machin was, if not in all, at least in most, respects true. At Mecheco, a town in the eastern extremity of the island, a small chapel was shewn, of which the following was the history given by the inhabitants. That the Englishman (Machin), on the demise of his wife, had erected a cross, with an inscription, requesting that should hereafter any Christian by chance resort to the island, a chapel might be built, in which masses should be performed for the soul of his Anne: that the above chapel was erected on the spot, and the cross, made of cedar, was preserved near the altar. This cross was always exhibited. It was, however, much diminished, on account of small pieces given gratuitously to different visitors, inasmuch that it was at last nailed to another and larger wooden cross, to preserve its form, and keep it together. This chapel had certainly greater marks of antiquity than any other building in that town. It was unfortunately washed away in that memorable flood which occurred in October 1803; so that, at this time, nothing remains to commemorate the event but the picture above alluded to, in the cattle hall.

De Barros, who considers the island as discovered by Gonçalves Zargo, informs us, that as soon as it was divided into captainships (Mecheco and Funchal), the first step taken by the new settlers was to set fire to the trees, the forest being every where impenetrable. Nothing can be better confirmed by every species of evidence than these facts, and that the island derived its name from the quantity of its wood. The word Madeira has the same signification as the Latin *materia*, from which it is only vernacularised, the Portuguese frequently substituting *d* for the Latin *t*, and transposing the *r* from its situation with its connecting vowel; of which we need give no more familiar instances than *padre* and *fradre* for *pater* and *frater*, when used in a spiritual sense. That *materia* is the classical term for forest trees, we have the authority of Cæsar in his Commentaries, who remarks of Britain, "*Materia cujusque generis, ut in Gallia, est; præter fagum et abietem.*" At this time the trunks of immense cedars are often discovered, but all the original trees themselves seem extinct, and, in the inhabited

part of the island, to have given place to chestnut trees. The land is supposed to have derived its great fertility from this conflagration, which is said, and with much probability, to have continued in different parts for seven years. But it is well known that no land could be fertilized by such an event for three centuries; and the account we have given of the nature and quantity of the vegetable stratum, joined to the abundance of water, and a favourable temperature, is sufficient to explain all the fertility it really possesses. Though the vines grow luxuriantly, and produce abundantly, wherever they have a sufficient depth of soil, plenty of water, and a favourable aspect, yet the corn-lands require all the cultivation and occasional fallows of other less favoured countries. At the same time, it is no small boast of the islanders that their country produces the best wheat, the purest sugar, and the finest wines in the world, besides being blest with the clearest water, the most salubrious air, the mildest climate, and a freedom from all noxious reptiles. Their wheat and sugar are such as are produced in the Mediterranean islands; but their wine, though originally brought from that source, infinitely surpasses all other in strength, delicacy of flavour, and dryness, besides the advantage of improving by being kept for any length of time, and even in southernmost latitudes.

The mode of producing a good crop of wheat, at a distance from the town, is by a previous cultivation of the common broom. This is cut for fuel, and, after a time, grubbed up, and burnt on the soil. By these means, a crop of wheat is insured for a succession of years, more or less, according to the soil; after which the same process is again resorted to. For this purpose, the seeds of the broom are collected, and generally bear the same price by measure as wheat. With all these assistances, the quantity of wheat produced is said not to equal a third of what is consumed, though maize is the principal food of the peasantry. Sugar is no longer cultivated as an object of traffic. Those fidalgos, who have plantations, still keep them up chiefly for their own use, and presents for their friends. Immediately after the sugar harvest, a small trade is carried on by manufacturing something like barley-sugar, called *rapaduras*, (probably *raspaduras*, meaning the raspings or scrapings of the fresh sugar,) with which most of the natives are accustomed to regale themselves and children at this season; but for common use, the island is supplied with sugar from the Portuguese settlements in the Brazils.

The wealth of the country consists in its wines, which are cultivated with a degree of industry proportioned to their value. To preserve the soil, it is found necessary to erect walls along the sides of the hills, at distances regulated by the declivity. These walls are, in some places, erected with prodigious labour. In aspects favourable for the growth of vines, if the soil has been previously washed away, so as to leave the bare rock, even here different stages have been erected, to which earth has been brought up, so as to form an artificial soil for this valuable production.

It will easily be conceived that such works as these cannot be accomplished without immense labour. When to this are added the difficulties of the roads, the vast expence and danger with which they are made, which, from the nature of the country, will in very few places admit of wheel carriages, and the consequent inconveniences of conveying every article from the town to remote parts of the country, and also of conveying the wine and other productions of the country to Funchal: when all this is taken into account, it will be readily understood that the cultivators of Madeira cannot be a slothful race. Yet because men, who have been hard at work from before sun-rise, are seen refreshing themselves

MADEIRA.

selves with sleep in the open air, and even on the beach, during the interval allowed for rest at noon-tide, they are often considered as indolent by strangers, who first view them after six hours' labour. Nor are the women less industrious. Those who are young enough climb the mountains to procure broom and brush-wood, which they bring to town, and sell for fuel. Others bring the produce of their gardens; whilst the elder ones are constantly employed at home in spinning or domestic concerns.

It is true, that the increased demand for labour in Funchal has produced a race, somewhat similar to our *long-shore* and *water-side* men in England, who labour much too hard, and support themselves under it with ardent spirits or wine. But this is far from the character of the people.

The country is cultivated by what are called by the French *metayers*, that is, by a peasantry who divide the produce with the land-owner. Considering the labour required for first preparing the land, and that the produce of the wine is reckoned as nothing till the third year, such a return to the cultivator is very unequal. He is usually allowed a small space for yams, or rather eddoes, *aron esculentum*, sweet potatoes, *convolvulus batata*, or other esculents. These he is expected to share with the landlord. In this there is said to be great collusion; but in the wine this can hardly be the case, on account of the tythes. The cultivators have, however, one very great interest in the land, and consequently a great inducement to engage in these operose undertakings. Whatever necessary improvements they make, become their own: hence the walls, the vines, and even their cottage, as far as is considered necessary, is their own property; and though, in entailed estates, a lease cannot be granted for more than nine years, yet the tenant cannot be dispossessed till he is paid the full value of his improvements. In proportion as the increase of commerce has rendered money of less value, the money-price of these improvements is advanced; and even the vines are estimated, not by number, but by their age and supposed fertility. Hence the tenant not only surveys the property he has acquired by his own labour or expence, but sees that property yearly improving by the common operations of nature.

The tythes of this, in common with the other Portuguese colonies, were given by the pope to the king of Portugal, as sovereign of the order of Christ. Out of them the clergy are paid, and for the most part very poorly. They formerly received all their revenue in kind; but, unfortunately for themselves, petitioned to have a moiety in money. In consequence of this, by the gradual diminution of the value of money, and increased value of every production, they are considerable losers. Some of them make a traffic of wine; and, on the whole, they are much less superstitious than in most Catholic countries. Their number, both secular and regular, is much less than is generally supposed. By some it is said not to exceed 300, including the monks and nuns. Of the former there is only one order in the island: the number of nuns is uncertain. There is a seminary in Funchal for the education of the clergy of the island, with something like an academic establishment, originally, we believe, formed by the Jesuits, who erected other schools in various parts of the country. The bishop retains his original number of pipes of wine, besides other emoluments, which render his situation more lucrative than the governor's. He is expected, indeed, to divide his revenue with the poor; and an instance is often mentioned of one whose benefactions exceeded his implied obligations.

The natives of Madeira are a very mixed race. Among the labouring class in the town we often recognise faces truly

English, and even English complexions. This is said to arise from the frequent intermixture of the two nations, not only by the English settlers, but by the constant arrival of English sailors. The other inhabitants, excepting the superior classes in some parts of the island, are a mixed race. Besides the colonists from the mother country, Moors in great number were at one time imported. Spaniards also resorted hither during the union of the two countries; and negroes have been purchased for this, as well as the other European settlements. The last were, however, few in number; their intermarriages with the natives fewer, so that but little vestige remains of their characteristic marks. On the whole, the male inhabitants may be called a comely race: they are, for the most part, about the middle size, well enough formed, with strong masculine features, hair, and complexions. The women are almost universally shorter than the comparative difference would lead us to expect. Such as are engaged in the laborious employments soon lose the few charms which youth might otherwise supply.

The animals, natives of the country, are, as in most mountainous parts, universally small. To an Englishman, their beef and mutton is also lean and tasteless; but those who are accustomed to warm climates speak of them in better terms. Of poultry, the common domestic fowls are small; but this is amply made up by their ducks and turkeys, the latter of which are not inferior to those of Norfolk. Pork is peculiarly fine; but the expence of feeding, or the warmth of the seasons, makes it such a rarity, that it is rarely produced excepting at Christmas festivals. It is true, hogs are found rambling about the towns, but very few are reared for porkers. Fish, particularly rock-fish, is plentiful and good of the kind; but the nature of the coast prevents the residence of many shell-fish.

The uneven form of the country renders the island productive of the European as well as more southern fruits; but it is a mistake that the true tropical fruits are readily produced. In the vallies are found guavas, bananas, and oranges. A single allegator pair tree has grown for several years, but rarely produces fruit. Pine apples are reared with great difficulty; and the *granadilla quadrangularis*, after spreading to a great extent, and flowering most luxuriantly, has not yet, we believe, produced ripened fruit.

The staple commodity of the island is wine, of which the average quantity made about ten years ago was reckoned between 30 and 40,000 pipes. More than half this is exported, principally to the British settlements in the East and West Indies. A quantity, comparatively very small, finds its way to London. Speculations in trade have lately increased this quantity: but there is reason to fear that the quality is not improved by it, as there is said to be constantly a difference between *barter-wine* and *bill-wine*; that is, between wine exchanged for marketable articles, and wine which is paid for by bills drawn at a short credit. The best wine grows on the south side of the island, and the best of that for the most part in the inferior parts, and on that side of the hill which points to the east. This advantage seems entirely attributable to warmth; the west being always cooled by the breeze or inbuh, which by noon constantly blows from that quarter. The north wine was formerly much undervalued, and principally consumed in the island, either as a beverage of the natives, or distilled into brandy. But the increased demand for the article has encouraged many of the merchants to mix a portion of north wine with the south; and the improvement of its price has given additional encouragement to improving it by cultivation. That the quality of the wine, however, depends principally on the aspect and soil, is pretty clearly proved by the superiority of the *gercial*. This, though originally

MADEIRA.

ginally produced from the Rhenish grape, is considered the strongest and richest of all the dry wines in the island. The best wine is almost always mixed with a portion of the *vinho tinto*. This is at first nearly the colour of red port, but from year to year grows paler. Hence, could we always ascertain the genuineness of the wine, the colour would be a considerable means of ascertaining its age. But the addition of the north wine will at any time lower the colour, and to the eye give the appearance of age. Certain it is that the vast demand of late years has nearly exhausted the island of old wine, so that those who wish for such a luxury, will do well to keep it themselves. This should be done, not in a cold underground cellar, but in the warmest part of a dwelling-house, and, if such can be procured, in an apartment open to the south.

The quantity of genuine Malmsey produced annually is very small, and in truth very uncertain, because a good deal is manufactured with refined sugar, and though greatly inferior to the genuine, is, if well managed, truly delicious. We have reason to believe these are the only sophistications of Madeira wine. The stories of the importation from Teneriffe and other places are certainly unfounded; at least such is the universal anxiety to preserve the credit of the island, that no quantity can be imported which would pay for the danger and expence.

The other exports from Madeira are trifling; they consist principally of chestnuts, walnuts, preserved citrons, and those occasional supplies of fresh provisions for vessels touching at the port, which are purchased here much dearer than in England. The imports consist of the greatest part of the provision of the island, excepting fresh meat, and even living sheep and oxen are imported with advantage from Barbary, and the Azores, or Western islands. From America they derive principally their wheat, Indian corn, and, in common with other Catholic countries, vast quantities of salt fish. From England they receive most of their wearing apparel, the quantity and value of which increase rapidly every year.

The crown of Portugal derives its revenue in part from a duty of 20 per cent. on the invoice value of all articles imported excepting provisions. But its principal revenue is from the wines. Besides the tythes, the farming of which is disposed of by auction every year, and which is every year purchased at a higher rate, a duty is imposed on all the wine as it is exported, and a sort of excise on what is consumed in the island. A revenue is also derived from the monopoly of snuff, cards, and soap. The aggregate is enough to pay all the expences of the civil, military, and ecclesiastical establishments, and to remit considerable sums to the crown. But there is always much uncertainty in the last. We have heard it stated as 5000 and 50,000; the latter we should conceive must be nearest the truth, when we reflect that a considerable part of the merchants' capital consisted at one time in the manner in which the revenue was remitted to Lisbon.

Of all the complicated mercantile questions, nothing is for the most part equal to that of the money in Madeira. From their intercourse with the English West Indies, or from some other cause, scarcely any thing is seen but Spanish silver coins, and by some unaccountable incidents, these have got the name of Portuguese coins. Thus the peltreen is called two testoons, and five of them are called a milrea, and though five peltreens are as exactly equal to a dollar as 5s. are to a crown, yet the Portuguese having no coin corresponding to dollars, for a long time the five peltreens were more valuable than the dollar, which last was hardly considered current in the island. Though this last absurdity is now done away, yet it has made no other difference in the names of their currency, excepting that the dollar has now the

name of milrea, in common with its representative five peltreens. But the coins in Portugal, whose names are thus usurped by the Spanish pieces, are intrinsically worth nearly 20 per cent. more than the latter. Hence, when an ignorant captain sells his cargo for so many thousand milreas, he usually finds his bills produce him about 20 per cent. less than he calculated upon. The currency and use of the dollar are gradually remedying this inconvenience.

The mode of government remittance to Lisbon was by giving Madeira milreas, for which the merchants gave their bills on Lisbon for the same number of milreas, payable at two years. By these means they paid about ten per cent. per ann. for the use of money for two years, at the expiration of which they often paid their bills as they became due, by issuing fresh ones. These transactions, though very convenient to the government, and still more so to the merchant, have often been productive of serious injuries, by inducing inconsiderate people to overtrade their capital, and on the least suspicion of their solvency, the crown has seized their whole; laying, as in England, violent hands on landed property, which has been sold by the government-debtor after the debt was contracted.

Besides the above duties on wine, the British consul and factory receive a certain sum on every pipe exported to any part of the British dominions, for the expences attending their establishment; for the relief of sailors left on the island; and of decayed merchants entitled to such a benefit. This fund should also support a clergyman and Protestant chapel, the erection of which would probably increase the reputation of the British nation among the natives, and might even support itself by voluntary contributions.

We have been thus particular in our account of this island, because, however inconsiderable in extent, it cannot be considered so in importance. Its climate productions, its situation by its proximity to Europe, and in the course to the East or West Indies, all render it interesting, but most of all, the present condition of the European continent, and the interest which England feels in whatever may facilitate her connection with her distant settlements. On this account it may not be amiss to add a few words on the advantage which England might derive from such a possession, and the consequences to the island of such a change.

Madeira is already so much connected with England, and the inhabitants of Funchal are so much anglicized, that in many of the Portuguese settlements it is humorously called *picbena Londres*, or little London. It is not only the quantity of English goods consumed in the island that benefits Great Britain, but the quantity exported from hence to the other Portuguese settlements. It is difficult to say whether England or Madeira is most benefited by this traffic. The only exchange that can be made for every article of luxury is wine, and the necessity of this commodity induces an increase of industry. Should the island become altogether English, it is probable that another source of wealth would be derived from English capital, which, expended in cultivating or improving fresh lands, might prove a profitable, though at first an uncertain, speculation. But whatever might be the consequences to England, the island could not but be benefited by all that is expended on its cultivation. This must however be accomplished by the manual labour of the natives, whose knowledge of their land enables them to turn to good account their industry, muscular strength, and great patience under meagre fare. But these are no longer sufficient without capital, since the price of labour is so much increased, and the parts easiest cultivated and most profitable to the labourer, are more generally occupied.

The present government is similar to that in the mother country,

country, to which all appeals are made, and to which any alteration in the existing laws are referred for decrees from the prince. It would not be safe suddenly to alter this system; but great pains are wanted to purify the fountains of justice. A people, accustomed only to obey by mandate, and to protest each other from the oppressions of government, could not at once fall into a legislation of which they are themselves a part. They must gradually be taught the blessings of liberty, by the certainty with which their property and persons are secured, and by the restoration of those privileges they once enjoyed; but which now exist only in name. These should be well understood and defined, and the utmost attempted at first should be a careful appointment of enlightened magistrates, or judges, as they are mostly termed, with a proper augmentation of their salaries, and the superintendance of a governor acquainted with the languages, laws, and customs.

From the heavy duties imposed by government, many expences are supported, which, according to the freedom of our constitution, are defrayed by the public, and regulated by commissioners of their own choice. We refer chiefly to the public works, viz. the building and repairing of churches, the improvement of the ports, and the construction and repair of roads and bridges. These last are paid only in part by the crown, the male inhabitants being obliged to perform certain labours in their different districts. If the work is considerable, a certain pay is allowed, but not at all adequate to the usual price of labour.

If the average amount expended on roads and bridges by government were lodged in the hands of commissioners chosen by the inhabitants; and if, in aid of this, a tax of two guineas *per annum* were laid on every horse; if the produce of this were added to the former fund, and the commissioners were authorized, as in England, to borrow money on annuities: by these means, the whole island might soon be intersected with roads, and united by bridges, so as to render every part accessible with ease. Hence the produce of the country would readily be brought to the towns, and from thence, by water, to different parts of the coasts; the gentry would have greater encouragement to remain a considerable part of the year at their country estates; the mansions on which be rendered universally convenient and elegant, and this example would soon extend to the wealthier cottagers, and even to the merchants and tradesmen, who would, as in England, be all ambitious of country residences. That all this may be accomplished, we have a striking example in the pavilion which M. de Carvalho has erected for himself, at the distance of about three miles east of Funchal. On a spot, at one time scarcely accessible, with only a single clump of trees, and almost without water, he now exhibits large sheets of water, extensive avenues of flowering shrubs, roads in every direction, and the prospect of an English *ferme ornée*.

In constructing roads in Madeira, the first object should, of course, be to preserve as level ground as is consistent with the nature of the country, by winding round the hills. But great care should be taken that the ascent is never interrupted: because, by such a provision, whatever is brought from the country can be conveyed without difficulty or labour; the back carriage must always be laborious, but mules with packs may be kept at different passes, and hired on the spot, like some additional horses in particularly steep roads in England.

One most serious evil must be immediately remedied whenever the island is allowed to use those blessings with which providence has indulged it. We have remarked the advantages derived from the height at which the rivers

rise. This not only gives the command of water before alluded to, but furnishes a power by which mills might be multiplied to any extent, or for any purpose. At present, the privilege of erecting water-mills is confined to a grandee, who never saw the island. Hence the mills, excepting near the town, are distant, nor is there any inducement to multiply them, as all must resort to them, however inconvenient. Nor is this all, in order to feed the mills near the town, a considerable quantity of water is lost, which, if expended on the higher grounds, would, in some seasons, add greatly to their fertility.

These are only a few of the benefits which England as a nation, and Madeira as a settlement, might mutually confer on each other. Besides this, a port might be constructed at Funchal, the bay of which, though invariably calm in the summer, is, during the winter, always uncertain, and sometimes dangerous. But the advantages to the individuals of both nations would be incalculable. The easy distance might induce many in delicate health to pass the winter in Funchal, where the thermometer is rarely lower than 60°, nor above 65°, and often stationary within doors for twenty-four hours. In the summer about 10° higher, and the air gradually cooler as you ascend the mountains. This city already, we are informed, has its theatres, its coffee-houses, and would soon have its library, its printing-presses, and its own gazettes. Though the expences of the table are perhaps equal to those of London, yet wine may be procured without an exorbitant duty; there are few other taxes, and the equipages of London will never be necessary in such a climate, nor perhaps manageable in such a country.

If ever the population of Madeira should be so considerable as to render labour cheap, or that employment should be wanted for many superfluous hands, the silk worm seems, of all others, the most promising article. For six, often for seven or eight months, they could feed on the trees in the open air without the danger of rain, and the description given of the rivers would at any time furnish streamlets which might turn mills sufficient for winding off the web. It is true, the attempts formerly made to introduce the white mulberry have hitherto failed, but this has been rather from a want of general concurrence in the cottagers, than from any difficulty in the soil.

The inhabitants of Madeira were reckoned at the last census about 100,000; of these nearly a tenth part are said to reside in or near the capital. Funchal has been well fortified since the English have arrived there, which was easily done on account of the barriers provided by nature. The regular force of the Portuguese government was 200 infantry, ill dressed and ill trained. The same number of artillery, whose appearance and discipline are highly respectable. There are three regiments of militia commanded by colonels of districts. These are drest in uniform at their own expence. The rest of the inhabitants, from the age of twelve years and upwards, are expected to furnish themselves with pikes or guns according to their abilities. In short, the whole government may be called military, a striking proof how little danger there is putting arms in the hands of citizens who are not oppressed, for in Madeira assassinations are few, and those few rarely among the lower class; and civil commotions have seldom existed for years past, and never proved sanguinary.

The other islands, included under the government of Funchal, are scarcely inhabited, excepting Porto Santo. This has its own governor, but is amenable to the governor at Funchal. Its produce is similar to Madeira, excepting that the wine is inferior. A good deal of barley is grown on this and the small islands, called *desertas*. Porto Santo also produces the water-melon in abundance, and

much superior in flavour to those which have been attempted in the larger island. Its fossilology is said to be very curious and valuable, but hitherto it has not been sufficiently explored. There is a tradition that it is inhabited by the offspring of degraded fidalgos from the mother country. It is certain that the natives have a different cast of features, being fairer, but by no means handsomer, nor so well formed. We have never heard their numbers ascertained. The salvages contain lime-stone, which is not to be met with in the other islands.

MADEIRA, or *Madera*, a river which rises in the government of Charcas in Peru, near Cochabamba, in S. lat. 13°, first called "Conderillo:" having received some smaller rivers, it changes its name into "Parapite." Hitherto its course is S.E., till it enters a lake situated in S. lat. 19° 50', after which it takes a northerly direction, with the name of "St. Miguel," afterwards "Sara;" about S. lat. 14°, it is called "Mamore;" and in S. lat. 10°, it leaves Peru, and enters Brazil, from which time it is called Madeira, till it discharges itself into the river of the Amazons in S. lat. 3° 15'. W. long. 60° 40'. Its whole course is about 1200 miles.

MADELA, a town of Asia, in Palestine; 192 miles S.E. of Jerusalem.

MADELAN, a town of Hindoostan, in the Subah of Agra; 10 miles S.E. of Kerowly.

MADELEY MARKET, a market town and parish situated in the hundred of Wenloch, and county of Salop, England. It is finely seated in a winding glen, through which the river Severn flows, at the distance of 147 miles from London, and 5½ from Shifnal. According to the parliamentary returns in 1801, this town then contained 291 houses, and 4758 inhabitants, being 2432 males, and 2326 females, of whom 1594 were found to be employed in various branches of trade. A navigable canal to the Ketley iron-works, which are among the most extensive in England, and also to a work for the extracting of fossil tar or petroleum from the condensed smoke of pit-coal, passes close to the houses. Over the Severn, in this parish, is thrown a noble bridge of cast iron, which was erected in 1779, and consists only of a single arch, 100 feet 6 inches in span, and 40 feet in height at the centre above the level of the base line. The road over this bridge is composed of clay and iron slag, 24 feet wide, and one foot deep. Iron top plates project from each side, and serve to support a very noble balustrade of cast metal. The weight of iron, in the whole, is 378 tons 10 cwt. This bridge contributes not a little to enhance the natural beauty of the romantic dale in which it is placed. (See *BRIDGE, Iron*, in vol. v. of this work.) At the foot of this bridge is the market-place, which is nearly two miles distant from its original situation. The market, since its revival in 1763, previous to which period it had been long discontinued, has been regularly held on Friday, and is, for the most part, well supplied with all the articles requisite for the sustenance of man. This parish includes the populous hamlets of Colebrook-dale, and Madeley-wood, which are remarkable for their extensive coal works.

MADENALLY, a town of Hindoostan, in the circar of Sollapour; 36 miles N. of Sollapour.

MADER, a town of Persia, in the province of Faristan; 20 miles N.E. of Estakar.

MADERAM-PULLI, in *Botany*, a name used by some authors for the tree whose fruit is the tamarind of the shops.

MADERNO, CHARLES, in *Biography*, an eminent Italian architect, was born at Biffona, in Lombardy, in the year

1556. He went at a very early age to Rome, where his uncle, Dominico Fontana, was, at that time in full employ as an architect. His genius for sculpture became manifest, and he was placed with an artist in that branch of the fine arts. His progress in modelling was such as led his uncle to confide to him the management of some buildings then in hand, which he executed with so much skill, that he was advised to devote himself entirely to architecture. At the death of Sixtus V. Maderno was appointed to design and execute the magnificent tomb for his interment. The public works which were carried on under Clement VIII. were chiefly committed to the care of this artist, and so high was his reputation in the succeeding pontificate, that, on the succession of Paul V. in 1605, he was appointed to finish the building of St. Peter's; his plans being preferred to those of eight competitors, and the work was placed under his direction. He was afterwards employed upon the pontifical palace on the Quirinal mount. Another work, for which he is celebrated, was the raising a fine fluted column found in the ruins of the temple of Peace, and placing it on a marble pedestal in the square of St. Maria Maggiore. His genius was by no means confined to architecture, he was sent by the pope on a commission to examine the ports of the ecclesiastical states, and afterwards surveyed the lake of Perugia, and surrounding country, in order to divert the inundations of the river Chiana. He was consulted upon most of the great edifices undertaken in his time in France and Spain, as well as in the principal towns of Italy. His last work of consequence was the Barberini palace of Urban VIII., which he did not live to complete. He died of the stone in 1629, when he had attained to the age of seventy-three. He had seen ten popes, by most of whom he had been regarded with favour. Gen. Biog.

MADERNO, in *Geography*, a town of Italy, on the S.W. coast of lake Garda; four miles N.E. of Salo.

MADETZ, a town of Walachia, on the Danube; 30 miles W.S.W. of Giorgiev.

MAD-HOUSE. By 14 Geo. III. c. 49. enacted to be in force for five years, and by 19 Geo. III. c. 15. which continued it for seven years farther, and by 26 Geo. III. c. 91. made perpetual, no person, on pain of 500*l.* shall entertain or confine, in any house kept for the reception of lunatics, more than one lunatic at a time, except such lunatics as are committed by the lord chancellor, &c. without a licence to be granted yearly by the college of physicians, within London and Westminster, and seven miles thereof, and within the county of Middlesex, and elsewhere by the justices in sessions. The licences are to be stamped with a 5*s.* stamp: every one who keeps a number of lunatics, not exceeding ten, shall pay the sum of 10*l.* and above ten the sum of 15*l.* and 6*s.* 8*d.* on every licence, as a fee to the secretary of the commissioners. No licence can authorize any person to keep more than one house. The commissioners, consisting of two justices and a physician, may visit licensed houses, and inspect their state as often as they think fit: on application to the commissioners for information concerning any confined person, the secretary is to search his books, and acquaint the persons applying with the name of the keeper in whose house the lunatic is confined. The keeper is required to give notice to the secretary, within fourteen days after receiving a patient, who is to file such notice; and every keeper admitting a person as lunatic, without an order under the hand of some physician or surgeon that such person is proper to be received, shall pay the sum of 100*l.*

No licence shall be granted unless the keeper enter into a recognizance in 100*l.* with two sureties in 50*l.* each, or

one surety in 10*l.*; on the usual conditions, for the good behaviour of the keeper. This act doth not extend to any of the public hospitals. This act contains various distinct regulations for such houses in London, Westminster, and within seven miles of the town, and in the county of Middlesex. By 48 Geo. III. c. 96. several provisions are made for the better care and maintenance of lunatics, being paupers or criminals in England. The first seventeen sections, and some others, relate to the building and endowing of lunatic asylums. As soon as such an asylum is ready, justices are, by warrant, to remove lunatics to it, and the parish is chargeable with an allowance. If the overseer neglects to inform the justices, and to apply for such warrant, he shall forfeit for every offence, not exceeding 10*l.* nor less than 40*s.* When lunatics are committed by justices under the 17 Geo. II. c. 5. the said justices shall order in their warrant that such lunatic, or mad person, shall be confined in such lunatic asylum, and not elsewhere; but if no lunatic asylum be established, they may order that such person be confined in any house duly licensed under the 14 Geo. III. c. 49. Where the lunatic's legal settlement cannot be ascertained, the justices may order such person to be confined in the lunatic asylum for the county or district within which such person shall have been apprehended, if there be any such, and not elsewhere; if there be none, in some house duly licensed under 14 Geo. III. c. 49, or in some other secure place, as directed by the 17 Geo. II. c. 5. And if such person have not an estate to pay and satisfy the reasonable charges of removing, and of keeping and maintaining and curing such person under 17 Geo. II. c. 5. then those charges shall be paid by the treasurer of the county within which such person shall be apprehended, out of the county rates, by order of two justices directed to him for that purpose. All lunatics, &c. shall be safely kept, nor be suffered to quit the said asylum, until the visiting justices shall order their discharge, and signify the same in writing under their own hands and seals: and if any servant or officer in such asylum shall, by neglect or connivance, permit such person to escape and to be at large, without such order, he shall, for every such offence, forfeit not exceeding 10*l.* nor less than 40*s.* In all cases, where by virtue of the 39 and 40 Geo. III. c. 94. any person shall be kept in custody, it shall be lawful for any two justices of the county where such person shall be so kept, to ascertain, by the best legal evidence that can be procured under the circumstances of personal legal disability of such lunatic, the place of the last legal settlement, and the circumstances of such person; and if such person is not possessed of sufficient property for his maintenance, to make order upon the parish where they shall adjudge him to be legally settled to pay such weekly sum for his maintenance in such place of custody as such court or his majesty shall appoint, as shall be from time to time directed and fixed upon by one of his majesty's principal secretaries of state; and where such place of settlement cannot be ascertained, such allowance shall be paid by the treasurer of the county where such person shall have been apprehended; but if it shall appear that such person is possessed of sufficient property as aforesaid, then such justices shall order the same to be applied to satisfy the expence and maintenance of such person in the manner directed by 17 Geo. II. c. 5.

MADIA, in Botany, was so named by Molina, in his Natural History of Chili. We are unable to conjecture, with precision, concerning the derivation of this word; it cannot surely be traced from *μαδα*, smooth, or without hair, because one species at least, if not the whole genus, is re-

markably hairy. Molin. Chil. 113. Willd. Sp. Pl. v. 3. 1951. Cavan. Ic. v. 3. 50. Juss. 450.—Class and order, *Synogonia Polygamia Superflua*. Nat. Ord. *Compositae discoideae*. Linn. *Corymbifera*, Juss.

Gen. Ch. Common calyx globose, of many leaves arranged in a double row, carinated; the eight exterior ones acute, and longer, approximating into a globe. Cor. compound, radiated; florets of the disk all perfect, numerous, tubular, five-cleft; those of the radius female, eight in number, ligulate, three-toothed. Stam. (in the tubular florets) Filaments five, capillary, very short; anthers cylindrical. Pist. (in the tubular florets) Germen ovate-compressed, most acute at the base, incurved; style simple; stigmas two. Peric. none, except the permanent calyx. Seeds solitary, the shape of the germen. Recept. naked. Down none.

Ess. Ch. Receptacle naked. Down none. Calyx double, the outer one of eight or ten equal leaves, longer than the inner one, which is composed of many leaves.

1. *M. viscosa*. Cavan. Ic. t. 298. (*M. mellosa*; Jacq. Hort. Schoenb. t. 302.)—Leaves sessile, almost lanceolate, hairy. Flowers axillary.—A native of Chili. It flowered in the Royal Gardens of the Escorial in August and September 1795.—Stem round, somewhat corymbose, branched, more than two feet high, covered with glandular hairs. Leaves scattered, sessile, but not embracing the stem, obtuse at the point, broader at the base, single-ribbed. Flowers yellow, strong-scented, on short footstalks, at the summits of the branches. Seeds black and shining.

2. *M. fativa*. Willd. n. 1.—Leaves linear-lanceolate, on footstalks.—A native of Chili.—Stem hollow, erect, round. Flowers on stalks, terminal.

3. *M. mellosa*. Willd. n. 2.—Leaves embracing the stem, lanceolate, hairy.—A native also of Chili. These two species are adopted by Willdenow from Molina without any further description than is now given.—Cavanilles also mentions them, but merely to say that *viscosa* differs from them both in having short roots, and sessile leaves, never embracing the stem.

MADIAN, or MIDIAN, in Ancient Geography, a town of Arabia, in the province of Hedsjas, which owes its name to one of the sons of Keturah, and was destroyed in the time of Abulfeda. It is seated at a small distance from the Red sea, which at this place is not more than 100 paces wide. The Arabs call it "Megar el Schuaid," or the Grotto of Schuaid, or Jethro: and they suppose that this is the place where Moses tended his father-in-law's flocks. Ptolemy calls it *Modiana*. N. lat. 28° 20'. E. long. 38° 10'. See MIDIAN.

MADINGA, in Geography, a river of America, in the isthmus of Darien, which runs into the Spanish Main, N. lat. 6° 22'. E. long. 78° 48'.

MADISON, a county of Virginia, bounded north-east by Culpepper, south by Orange, and west by Shenandoah county; about 30 miles square, watered by the Rapid Ann and Robson rivers, and containing 4886 free inhabitants, and 3436 slaves.—Also, a county of Kentucky, adjoining Fayette, Clarke, Lincoln, and Mercer counties. It contains 10,380 inhabitants, of whom 1688 are slaves. The chief town is Milford.—Also, a small post-town of Amherst county, Virginia, on the north side of James's river, opposite to Lynchburg; 150 miles W. by N. of Richmond.

MADISON'S Cave, the largest and most celebrated cave in Virginia, situated on the north side of the Blue Ridge. The cave extends into the earth about 300 feet, branching into subordinate caverns, which terminate, after ascents and descents, in two different places, or basons of water of unknown

known extent, nearly on a level with the water of the river.

MADISTERIUM; *Μαδιστεριον*, a name given by the Greeks to an instrument intended to keep the skin smooth, by eradicating the hairs.

MADMAR, in *Geography*, a town of Persia, in Khorasan; 12 miles W. of Herat.

MADMEN. See **LUNATICS**.

MADNESS. See **MENTAL Derangement**.

MADNESS from the Bite of rabid Animals, the *Rabies canina*, and *Hydrophobia* of medical writers, will be found described at length under the latter title. The term *madness*, as applied either to the disease in the dog, or other rabid animal, or to that of the human species, when bitten, is an absolute misnomer, and has led to some important popular errors both of opinion and practice; and ought therefore to be discarded. There is neither the violence in the rabid animal, which the term implies; nor the derangement of intellect, or violence in the hydrophobic patient, which has been inferred from the appellation. Yet these mistaken notions have led to the practice of permitting dogs, actually rabid, to go loose, and inflict mischief on the public, as well as to that of murdering sick men by suffocation, from an apprehension of the ungovernable fury which it has been supposed would ensue. See **DOG** and **HYDROPHOBIA**.

MADNETI, in *Geography*, a town of Hindoostan, in Mysore; 18 miles E. of Bangalore.

MADNING-MONEY; old Roman coins, found about Dunstable, are so called by the country people; and have their name from *magintum*, used by the emperor Antoninus in his Itinerary, for Dunstable.

MADODENQUIK, in *Geography*, a river of New Brunswick, which runs into the St. John, N. lat. $46^{\circ} 19'$. W. long. $67^{\circ} 34'$.

MADOLAND, a town of Kemaon; 5 miles N.W. of Kerigar.

MADOMGUNGE, a town of Hindoostan, in Bahar; 7 miles S. of Bahar.

MADONA, a small island in the Mediterranean. N. lat. $36^{\circ} 31'$. E. long. $26^{\circ} 49'$.

MADONA di Scopia, a town on the east coast of the island of Zante; 2 miles S.E. of Zante.

MADONIA, a mountain of Sicily, in the valley of Mazara; 35 miles S.E. of Palermo.

MADONNINA, in *Commercia*, a silver coin of Genoa, of which there are the double, single, and half, at 40, 20, and 10 soldi. The double *Madonnina* (the single and half piece being in proportion) weighs 5 dwt. $19\frac{1}{2}$ gr., contains, in pure silver, 116.2 grains, and its value is 1s. $4\frac{1}{4}$ d. sterling. The impression is a whole length figure of the Virgin standing, with her head encircled by stars: legend, **SUB TUUM PRÆSIDIUM** (under thy protection), with the date; and round the figure, **NE DERELINQ. NOS** (do not forsake us): reverse, arms of Genoa; legend, **DUX ET GUB. REIP. GENU.** (doge and governor of the republic of Genoa).

MADOO, in *Geography*, a small island in the East Indian sea. S. lat. $7^{\circ} 31'$. E. long. $122^{\circ} 18'$.

MADOOGARRY, or **MADOOGARY**, a town of Hindoostan, in Coimbatore; 6 miles S.S.W. of Coimbatore.

MADOOR, a river of Hindoostan, which rises in the Mysore, about 20 miles N.N.W. of Sera, and runs into the Cauvery, 36 miles below Seringapatam.

MADOOSAND, a town of Hindoostan, in Rohilcund.

MADORE, a town of Hindoostan, in Mysore; 8 miles N. of Seringapatam.

MADRAPOUR, a town of Bengal; 20 miles S.E. of Boglipour.

MADRAS, FORT ST. GEORGE, or, as it is called by the natives, *China-patam*, a town of Hindoostan, on the coast of Coromandel, and close on the margin of the sea. It was about the year 1620 that the English East India company obtained leave of the king of Golconda to settle at Madras-patan, where they were permitted to build the fort called St. George; which place has ever since been the company's general factory for their trade to all parts east of Cape Comorin. (And. Hist. Com. vol. ii. p. 6. folio.) Others say, that Madras was settled by the English about the year 1640; and it is also said, that the town was built in the reign of Charles II. by order of the East India company, under the superintendance of sir William Langhorne. As he placed it in the middle of a sandy desert, altogether dry, and where there was no water fit for drinking, except what was fetched from the distance of more than a mile, people were curious to know what reasons could have induced him to make so bad a choice. His friends pretended that his view was to draw thither all the trade of St. Thomas, which has actually been the consequence; while his enemies imputed it to a desire of continuing in the neighbourhood of a mistress he had in that Portuguese colony. In the rainy season, the sea threatens destruction on one side, while the river, menacing an inundation, is no less terrifying on the other. From April to September the sun's heat is scorching; and if it were not mitigated by the sea-breezes, the place would not be habitable. In the vicinity of the city the soil is so dry and sandy, that it does not produce so much as a blade of grass spontaneously, nor any corn without great labour of culture. The roots, herbage, and vegetables, consumed in this place, are brought from a considerable distance. It is still a more unfavourable circumstance, regarding the place in a commercial view, that, in common with all the other European settlements on this coast, Madras has no port for shipping; the coast forming nearly a straight line; and it is also incommoded with a high and dangerous surf that breaks upon it, and induces the necessity of using the boats of the country for the purpose of landing. These are of a singular construction, being formed without ribs or keel, with flat bottoms, and having their planks sewed together; iron being totally excluded throughout the whole fabric. By this construction they are rendered flexible enough to elude the effects of the violent shocks which they receive by the dashing of the waves, or surf on the beach; and which either oversets or breaks to pieces a boat of European construction. No port for large vessels occurs between Trinkamaly and the Ganges, that is, in an extent of 15 degrees; so that the comparative proximity of the former to Madras and Pondicherry renders it a capital object, both to the English and French. Nevertheless, Madras has been reckoned among the richest ports in India. Notwithstanding local disadvantages, the company find it convenient in other respects, especially as to their trade in calicoes, chintzes, and muslins, diamonds, &c., and in putting off their European wares most sought after there, viz. stockings, haberdashery, gold and silver lace, looking-glasses, drinking-glasses, lead, wines, cyder, cheese, hats, stuffs, ribbons, &c.

Madras is divided into the White Town and the Black Town. The first of these, known in Europe by the name of Fort St. George, is inhabited only by the English. The fort lies N.N.E. and S.S.W. in the middle of the White or English Town. It is a regular square, about 100 yards on each side. The White Town is about a quarter of a mile

length, and half as much in breadth. North of the fort are three straight streets, and on the south an equal number. The houses are flat-roofed, built with brick, and covered with a plaister made of sea-shells, which no rain can penetrate. The walls are thick, and rooms lofty; but few of them exceed one floor, though some are raised a floor above the ground. Opposite to the west gate of the fort is a barrack, for lodging the company's soldiers when off guard; and adjoining to this, a very convenient hospital. At the other end of the barrack is a mint, where the company coin gold and silver. There is a town-house, where the magistrates assemble, and in which courts of justice are held. The whole is encompassed with a strong wall of the same stone with that used for building the fort. This is defended by batteries, bastions, half-moons, and flankers; the whole being mounted with about 200 pieces of cannon, and three mortars, including the guns on the outworks, besides field-pieces. Round it, on the west side, is the river, by which and a battery it is defended. South of the White Town is a little suburb, the residence of the black watermen, who are its sole occupants. This consists of little low thatched cottages; and beyond it is an outguard of blacks, to give notice of any danger. Indeed it cannot be well attacked, except on the south and north sides; for towards the sea, the swell and surges are a perfect security. Madras is now, perhaps, says major Rennell, one of the best fortresses in the possession of the British nation; and although not so regular a design as Fort William, in Bengal, yet from the greater facility of relieving it by sea, and the natural advantages of ground, which leave the enemy less choice in the manner of conducting his attacks, it may, upon the whole, be deemed at least equal to it.

The Black Town, called *Madras*, and sometimes *Chinapatam*, was formerly quite open, but, since the year 1767, it has been surrounded with a strong wall, and a ditch full of water. The wall is of brick, 17 feet thick, with bastions at proper distances. On the west is a river, and on the east the sea; north is a canal cut from the river to the sea, which answers the purpose of a moat on that side. The town is a mile and a half in circumference, and might be reckoned a strong place, with a garrison proportioned to it; and attention has lately been given to this circumstance, so that it neither wants men, nor stores and provisions for its security and defence. This town is inhabited by Gentoos, Mahometans, and Indian Christians, *i. e.* Armenians and Portuguese, and also a number of Jews. The streets of the Black Town are wide, and sheltered with trees from the sun's heat. Some of the houses are of brick; the others are mean cottages. The abbé Raynal reckons the whole number of inhabitants of Madras at 300,000.

The town is in general very populous, each of the cottages containing a family of seven, eight, or nine persons; and yet, numerous as they are, and mean in their appearance, the place abounds with wealth. The bazar or market is every day crowded, and exchanges of property are made to a great amount, which they transfer with as much facility as it is done on the Exchange of London. In the Black Town is an Armenian church, with several little pagodas or Indian temples, to which belong a number of priests and female choristers. From the beginning of March 1777 to the end of February 1778, the temperature of this coast was upon a mean $81^{\circ}.4$; that of the standard is $81^{\circ}.3$; the greatest heat was 102, the least 64° . Kirwan. N. lat. $13^{\circ} 5'$. E. long. $80^{\circ} 25'$.

The company's lands, or Jaghire, extend from Madras to the Pallicate lake, northward; and to Alemparvé, south-

wards; and westward, beyond Conjeveram; that is, about 108 British miles along shore, and 47 inland, in the widest part. This Jaghire is understood to be held in perpetuity. It contains about 2440 square miles, and its revenue is reckoned at about 150,000*l.* per annum. Rennell's Mem.

MADRE DE DIOS, an island in the South Pacific ocean, near the coast of Patagonia, 180 miles in circumference. S. lat. 51° . W. long. $77^{\circ} 46'$. See also RESOLUTION.

MADRE de Popa, a town with a convent, in South America, in the province of New Grenada, situated on the river Grande, or Magdalena. The pilgrims in South America resort in great numbers to the convent in this place, regarding it with a veneration similar to that with which Santa Casa is respected in Europe. Many miracles are reported to have been wrought here by the holy virgin, in favour of the Spanish fleets and their sailors, who are therefore very liberal in their donations at her shrine; 34 miles E. of Carthagena. N. lat. $10^{\circ} 51'$. W. long. $76^{\circ} 15'$.

MADREBOMBO. See SCHERBRÖ.

MADREPORA, MADREPORE, in *Natural History*, a genus of the class Vermes, and order Zoophyta; animal resembling a medusa; coral with lamellate star-shaped cavities. There are about 120 species scattered through the different seas on the globe, some of which, as will be noted, are common to our coasts. These are usually distributed into five subdivisions, as follow:

A. Composed of a single Star.

Species.

*VERRUCARIA. Star orbicular, flattish, sessile, with a convex disk full of tubular pores and a radiate border. This species is found in the Red, Mediterranean, and Northern seas, adhering to marine vegetables, and the softer zoophytes. It is the size of a split pea, and appears an intermediate species between the madrepora, tubipore, and millepore; white or yellowish, with aggregate tubes on the disk, like florets of a composite flower, and a flattened striate border, like the rays of these flowers.

TURBINATA. This is described as turbinate, sessile, smooth, with an hemispherical concave star. It is found in Gothland and Campania.

*PORPITA. Without a stem; the star is convex, orbicular, with a depressed centre, beneath flat, margined, smooth.

FUNGITES. Orbicular, convex, with simple longitudinal laminae or gills, beneath concave and papillous. It is found in the Indian and Red seas; sometimes with and sometimes without footstalks; is from one to six inches in diameter; white, with a concave centre, and rough beneath; the gills are acute, alternately shorter and irregularly ferrate.

PATELLA. Without stem; gills granulate at the sides, denticulate at the margin, and placed in a triple order; the third reaching from the centre to the margin. Inhabits the Mediterranean, and is about an inch and a half in diameter. All the gills are denticulate at the margin, and very rough at the sides: the younger specimens are flat, but the full-grown ones convex.

CYATHUS. Clavate, turbinate, with a tapering base; star rather conic, with a double, prominent, jagged centre. It inhabits the southern coasts of Europe; it is about two inches long, and three quarters of an inch in diameter. In substance it is white and hard; it has about forty gills, with as many intermediate smaller ones, the latter reaching to the margin, but not extending to the centre like the larger ones.

B. With

MADREPORA.

B. With numerous separate Stars, and continued Gills.

Species.

PILEUS. Without stem, oblong, convex, beneath concave, with longitudinal rows of concatenate stars; gills crowded, abbreviated. This species inhabits the Indian ocean. In the furrow along the middle is a line of stars with their gills disposed on each side in a radiate form; under these on each side are two rows of stars, as it were linked together, with their rays nearly parallel and pointing upwards and downwards; margin all round terminated by sharp erect laminae, or gills.

CRISTATA. Foliaceous, crested, with rows of stars impressed in the centre; the foliations broad and flattish. It inhabits the Indian and South seas.

LACTUCA. Sessile, with large, crowded, frondulent stars, the fronds perpendicular, waved, jagged. This is a rare species, but is occasionally found in the American ocean.

FICOIDES. This species is foliaceous, crested, with scattered stars; the lateral foliations flattish, marginal ones carinate; gills foliaceous. It inhabits the South sea.

ACEROSA. Foliaceous, crested, with scattered stars; lateral foliations flat, terminal ones subcarinate; gills needle-shaped.

LICHEN. Foliaceous, crested, with obconic rounded rows of stars, and very acute, carinate, subflexuous, obliquely placed foliations. Found in the South sea.

AGARICITES. This is without stem; with carinate grooves and concatenate stars. Found in the American islands; is about five or six inches in diameter; cinereous in colour, consisting of various divergent semiorbicular gills, with numerous serpentine grooves, in the bottom of which are placed the stars.

ELEPHANTOTUS. Somewhat turbinate, with granulous parallel gills, and scattered prominent stars within. Inhabits the Indian ocean, and is an intermediate species between the *Lactuca* and *Agaricites*; it resembles a thin, sessile, undulately curled lamina, with stars disposed nearly in the form of a quincunx.

CRUSTACEA. Crustaceous, with a flat stellate surface, composed of thick-toothed concatenate rays. Inhabits the American ocean; obtusely conic, with the stars disposed in a quincunx form.

INCRUSTUM. This is unequal, with prominent, conic, truncate, hollow stars, which are distant at the tip and lamellate within. It inhabits the Red sea. Stars about the size of a pea at the base, and half the size at the tip.

EXESA. Crustaceous, with reticulate, concatenate stars, and abrupt, conic, acute interstices. Inhabits the Pacific ocean. It is white, with conic warts, smooth at the tip; gills rough, unequal.

FILAGRANA. This is without stem, simple, with a very thin, serpentine, labyrinthic star, with an acute future, and flat perforated spaces. Found in the Indian ocean.

NATANS. Simple, without stalk; star serpentine, labyrinthic, with the disks of the undulations very broad; future obtuse, coral porous. Inhabits the Indian and American seas.

ANTIOPHYLLUM. Simple, with an ovate stalk; star terminal, hemispherical, concave, with radiate thicker gills at the bottom. It inhabits the Mediterranean.

C. With numerous united Stars.

Species.

LABYRINTHICA. Without stalk; star with serpentine undulations, and obtuse future. Found in India, and like-

wise in South America; very variable in form, and frequently many feet in diameter. In the Caribbee islands it is often burnt into lime; gills denticulate, and jagged at the ends.

SINUOSA. This has spreading, short, flexuous undulations, and unequal jagged dissepiments, the prominent undulations mostly doubled; gills denticulate. Inhabits South America.

MEANDRITES. Without stalk; star with serpentine undulations and acute future. Inhabits South America and the Mediterranean. The undulations are larger and looser than in the *Labyrinthica*, and the substance is more solid, and nearly stony; the centres of the stars radiate with thick gills.

AREOLA. Without stalk; the undulations are dilated, and in some places doubled, with narrow truncate margin; gills crenate. This is found in India and South America; is of a rosy colour, and smooth beneath.

ABDITA. Subglomerate, with star-shaped, angular, obconic foliations and simple undulations; gills narrow, with crenulate teeth. This is thought to be a variety of the *Favosa*, to be hereafter described.

PHRYGIA. With long narrow undulations, and perpendicular prominent ones, the dissepiments simple, lamellate, lobulate; gills rather remote. Found in the Southern ocean. The undulations are sometimes straight, and sometimes flexuous.

REPANDA. This has prominent undulations thickened; the dissepiments simple and hardly united; gills numerous, most of them thickened within.

AMBIGUA. The undulations of this species are star-shaped and flexuous, the prominent ones are thickened, dissepiments simple and thickish; the gills are distant.

DÆDALEA. This has deep, short undulations, and perpendicular prominent ones; the dissepiments jagged-gills ferrate. Found in the East Indian ocean.

GYROSA. This species is cellular, with doubled foliaceous, prominent undulations, and simple dissepiments; the gills are foliaceous and equal. This is one of the smoothest of the genera, and covered with numerous cells.

CLIVOSA. The undulations in this are narrow at the base with equal dissepiments, the prominent ones are simple and thickish; the gills are alternately abbreviated. It inhabits South America; is rounded and nodulous.

CEREBRUM. This is known as the *Brain-stone*; it is nearly globular, with very long tortuous undulations, and ending with flattish prominent ones. It differs in size from two inches to two feet in diameter.

INVOLUTA. The undulations in this are dilated at the base, and are short with nearly equal dissepiments; the prominent ones are simple.

IMPLICATA. Undulations rounded, and nearly perpendicular with equal and broad dissepiments; the prominent ones are doubled and broad.

COCHLEA. In this the undulations are spiral; the star is simple or double, with a punctured centre; the rays are ferrulate. It inhabits Tranquebar, and is a species that is between the *Testacea* and the *Zoophyta*.

D. Aggregate, undivided, with distinct Stars, and porous, tuberculous, prominent Undulations.

Species.

FAVOSA. The stars, in this species, of the fourth division, are angular, concave, connected. It inhabits the Indian ocean. It is white and striate at the sides; when divided transversely it appears reticulate, with unequal pores and spots; gills toothed.

CAVATA.

MADREPORA.

CAVATA. This is subglomerate, with star-shaped, angular undulations, and simple narrow divisions; the gills are denticulate.

BULLIENS. In this the stars are distant, round or oblong, unequal and elevated at the margin, the interstices are formed with somewhat concave, radiate wrinkles.

ANANAS. With annular convex stars, which are concave on the disk. It inhabits the Mediterranean and South American seas, and is frequently found in a fossil state. It is gibbous, and when dissected transversely, resembling a white net with hexangular spots, including a white ring, and striate between the net and the ring.

HYADES. With crowded, obconic, rounded, and somewhat angular stars, and thick porous divisions; the centres are flattish and convex.

SIDEREA. With crowded, rounded, and angular stars, and thick, rather convex, divisions; alternate gills nearly united at the margin; centres simple.

GALAXEA. This has rather crowded impressed stars, and thick, flattish, nearly distinct divisions; the gills are very thin, and the centres a little worn. The gills are formed by fours, reaching to the centre; the three intermediate ones are connivent at the base.

PLEIADES. The stars are roundish with acute, elevated margins; the interstices are concave, smoothish, and in some parts a little cavernous.

PAPILLOSA. This is somewhat aggregate; the stars are cylindraceo-papillous, with thickened, rounded, oblique margins. It resembles the *Muricata*, of which it may probably be the embryo, but the papillæ are contiguous, and disposed in a single row.

RADIATA. Stars cylindraceous, with elevated margins, the interstices broad, concave, and radiate with grooves.

LATEBROSA. Stars roundish, with many rays and elevated margins; the interstices are radiate with grooves, a little narrowed and unequal. It is found in the West India islands.

POLYGONA. With minute crowded stars, intermixed with larger perforated ones, the bottom concave, cylindrical. It inhabits the Indian sea, and resembles a white crust about two inches thick; the smaller stars are minute, rather obtuse, and twelve-rayed, the larger ones as big as the end of a finger, more gibbous, with an empty cavity between them.

ARENOSA. This, which has contiguous, flattish, ochraceous stars, is found in Algira; is white, with large stars, sometimes a little elevated and verrucose.

INTERSTINCTA. With round, distant, immersed cylindraceous stars; the interstices are porous. It inhabits India, America, and Norway.

SPONGIOSA. This is somewhat dilated, with craggy foliations, obtuse above and flat beneath; the stars are funnel-formed, deep, and unequal.

FOLIOSA. This is likewise dilated, with foliations somewhat craggy and verrucose above, beneath flattish; stars unequal and small. It is found in the Indian ocean. It is large and rosy.

PORCULATA. The stars of this species are obconic, with acute margins, and in some places remote; the interstices are smooth, and the gills every where granulous. It is very rare, and is of a greyish-white.

STELLULATA. With round, distant, equal cylinders of stars elevated at the margins; the interstices are rather flat and rough.

ASTROITES. This is sub-globular, with very numerous immersed stars, the interstices are porous. It inhabits South America, in large masses, and is whitish.

STELLATA. Solid, rough outwardly, with scattered convex stars impressed in the middle; it inhabits the Indian ocean, is grey with rough minute points.

NODULOSA. This has crowded obconic stars; the interstices and gills are rather sharp and roughish; the coral is a little nodulous.

ACROFORA. Hemispherical, with crowded, annular, prominent, crenate stars, which are small, elevated with a deeper centre.

CAVERNOSA. The stars in this species are immersed, salver-shaped with a striate border, and separated by an elevated future; it is found in South America and the Mediterranean; the stars are elevated, and the future forms a pentagonal net-work.

PUNCTATA. This has crowded star-like points composed of ten dots; inhabits the European ocean, and also the Mediterranean; it is rounded, white, friable, with small unequal star-like dots.

CALYULARIS. In this the cylinders are united; the stars are concave, with a rather prominent centre; it inhabits the Mediterranean; is roundish and brown, with distinct lateral cylinders, transversely wrinkled outwardly; the inhabitant is an actinia, and is a large and very sluggish animal.

TRUNCATA. Joints turbinate, proliferous, coalescing at the extreme margin; stars truncate, with a concave cylindrical disk. It is found in a fossil state; a little rugged, with joints of equal length and breadth.

STELLARIS. Joints proliferous, central, solitary; stars connected by a dilated margin; found fossil on the shores of Gothland; stems simple, parallel, erect, as thick as a finger, and four or five inches long; bark obsoletely striate, with cup-shaped joints an inch long.

ORGANUM. Corals cylindrical, smooth, distant, combined, with deflected membranes. It inhabits the Red sea, but is more frequently fossil; the cylinders are parallel, and as thick as an oat-straw.

DIVERGENS. Sub-globular, with divergent cylinders standing out beyond the surface twice their diameter; this is also found in a fossil state.

* **MUSICALIS.** Corals cylindrical, striate, distant, united by numerous transverse dissepiments; it inhabits the Indian ocean, and is sometimes cast on the Irish coasts, and often found petrified; coral white, and often very large.

DENTICULATA. Stars unequal, the gills have an elevated margin, the larger ones acute with a process at the base; the interstices are grooved.

FAVEOLATA. The stars of this species are somewhat angular, many-rayed, and here and there doubled when cut longitudinally.

RETEPORA. The stars are rather angular with filamentous gills, and reticulate when cut longitudinally.

ROTULOSA. Stars cylindraceous, with few rays; the gills erect and acute towards the margin, with an erect spine at the base.

CESPIIOSA. Corals round, slightly branched, striate, approximate, with turbinate concave reticulate stars; the coral is white, stony, very large, and often soft; it is frequently found in a fossil state.

FLEXUOSA. Corals cylindrical, rough, flexuous, approximate, with concave striate stars. Found cast on the shores of the Baltic.

FASCICULARIS. The corals are straight, cylindrical, glabrous, and divergent. It is found in the Indian ocean; white, stony, solid, unequal; frequently found fossil in different parts of Europe.

PECTINATA. The stars of this species are orbicular, with a tumid, dilated, radiate margin, the interstices are dotted.

MADREPORA.

dotted. It is found in Silesia; the stars are flat, with about 30 unequal denticulate gills.

ROTULARIS. The coral of this species is of many shapes, with solitary, orbicular, flat, unequally radiate stars, with a smooth, flat, and hardly prominent margin. This is found in the Red sea, frequently growing to other marine substances, white, solid, sub-globular, or flattened, the stars about a line in diameter.

TUBULARIS. In this the tubes are cylindrical, very entire, a little prominent and expanded into an unequally radiate star. This is frequently found fossil; the tubes are about the size of a crow-quill; the stars have six thicker gills, between each of which are three lesser ones.

MAMILLARIS. Stars orbicular, prominent, wart-like, excavated. Found near Frankfort in a fossil state; the stars are without a border.

PATELLOIDES. Glabrous, stars large and many-rayed, being a little elevated with a minute centre. This is found fossil; the stars have from 30 to 40 thick equal rays.

GLOBULARIS. Stars large, rounded, equally rayed, with a large perforated centre.

FILUM. The stars in this species are rounded, large and somewhat crowded, with a very minute and partly excavated centre. This is found in a fossil state near Basle.

PERFORATA. Stars crowded, minute, excavated, with perforated gills. The coral is sometimes hemispherical, and nearly a foot in diameter; the stars are twelve-rayed.

VERMICULARIS. Stars with unequal, undulate, smooth rays; it is found fossil; the stars have about eight principal rays, some of them are forked.

***ARACHNOIDES.** Stars crowded, minute, flattened, with subundulate, short, equal rays. It is found fossil; coral hemispherical; the stars have twelve contingent rays.

UNDULATA. Stars large, elevated, with elongated curved rays; it is found fossil; stars about half an inch wide, with 24 rays.

SOLIDA. Stars every where contiguous, with united membranaceous margins. It inhabits the Red sea, where it forms vast rocks, and is used in building, and burnt into lime; the stars are concave, with a very thin brittle margin; the centre is orbicular and rough, with a row of small tubercles.

***MONILE.** Stars funnel-formed, without disk, covered with gills and divisions; gills equal, radiant, denticulate, and continued into the next star. Found in a fossil state in Arabia; stars as large as a pea; the centre less than a mustard-seed.

DÆDALICA. The stars of this species are somewhat hexagonal, with united reticulate divisions toothed internally, and at the margin. Inhabits the Red sea; the stars are snowy, very thin, and toothed within.

MONOSTRIATA. Divisions between the old stars elevated into rough lanceolate tongue-shaped processes; this is found in the Red sea; is spongy, tough, snowy.

CONTIGNATIO. This is flattish and orbicular, with linear stars at the circumference tending to the centre, the middle ones ovate, divaricate, and nearly contiguous. An inhabitant of the Red sea; is sometimes found a foot in diameter.

CRISTATA. Corals ventricose-conic, smooth, but rough towards the tip; stars angular-rounded, labyrinthic, and furnished with alternately shorter rows of gills. Is found on the shores of China.

RUS. Unequal, with spongy papillæ, and superficial flattish distant stars. It inhabits the Red sea.

CUSPIDATA. Corals conic, grooved; stars turbinate, with straight, elongated, acute gills. It is found in China.

E. Branched, with distinct Stars and tuberculous porous Undulations.

Species.

PORITES. Slightly branched, composite, rough, with substellate crowded pores. Inhabits India and South America; is of a clear white, outwardly often grey; the branches are patulous, obtuse, and rough, with eminent dots.

DIGITATA. Branches clavate, flattened; stars scattered, six-rayed, with a projecting, vaulting, upper margin. Inhabits the Indian ocean; resembles the last; the coral is white, outwardly yellowish-grey.

DAMICORNIS. This species is very much branched; the branches are tapering and subdivided; stars crowded, blind, and ciliate. It inhabits Africa and India.

VERRUCOSA. This also is very much branched, and the branches are obtuse, and furnished with numerous simpler wart-like sub-divisions; the stars are scattered, and also crowded and ciliate.

MURICATA. This is a composite and sub-imbricate species, with obliquely truncate prominent ascending stars; there are six varieties of this species, viz. 1. With long pointed branches, and without smaller sub-divisions. 2. With divaricate branches, and short divergent pointed sub-divisions. 3. With ascending straight branches and sub-divisions. 4. With decumbent lower branches, and ascending, short, acute sub-divisions. 5. In this variety the branches are united into a palm at the base, with divergent sub-divisions. 6. This has numerous divergent branches and sub-divisions; the cylinders of stars are turbinate, with thickened rounded margins. Inhabits India and South America.

FASTIGIATA. In this the stars are decorticated outwardly. Inhabits South America; is white and nearly a foot high.

RAMEA. The branches are striate, cylindrical, truncate, with terminal stars; it is found in the Indian, Mediterranean, and Atlantic seas, is about two feet high; stony, ferruginous, and marked with fine longitudinal striæ, some of which are undulate.

OCULATA. This is tubular, glabrous, flexuous, obliquely striate, with alternate branches and concave stars pointing two ways. Inhabits the Indian ocean, and is found in European countries in a fossil state; the coral is white, perforated within.

VIRGINEA. This is sub-dichotomous, straight, solid, with alternate eminent stars. It inhabits the Mediterranean, American, and Norway seas; it is milk-white, and about the thickness of one's finger.

ROSEA. This species is, according to its name, of a rose colour, much branching, with numerous prominent margined stars; it inhabits the Indian ocean, and is about four inches high; the coral is of a beautiful rose-colour when recent, and afterwards fading to a paler tinge; the branches taper towards the base.

HIRTELLA. Stars every where alternate, prominent, with exerted acute gills. It inhabits the Indian ocean, and is white.

LIMITATA. Branches a little flattened, with scattered six-rayed stars, equal at the margin.

BOTRYOIDES. With thick, fastigiata, obtuse, clustered branches, and reticulate craggy undulations.

GRANOSA. This species is a little branching, crested, and somewhat fingered; with the branches obtuse; all the undulations are acutely carinate; the stars are linear and irregular.

PROLIFERA.

PROLIFERA. This is sub-dichotomous, coalescing, with stars at the side proliferous, terminal, concave. This is an inhabitant of the Norway sea; it is white and very solid; the stars are funnel-formed with about eight gills.

SERIATA. This species is branching, with subulate subdivisions and star-like pores in longitudinal rows. Inhabits the Eastern ocean; it is white, stony, about the size of a large quill, and nearly a foot high.

CACTUS. This has compressed, divergent, dichotomous branches, carinate at the edge; the sides with contiguous stars. It is found fossil in Arabia; is about a foot high; the branches are a little erect, and in transverse rows.

CORYMBOSA. The branches of the corymb are thicker at the tip and marked with prickly striæ; the stars are terminal, and solitary; the branches are as thick as a finger; the stars are an inch wide.

GEMMASCENS. This species has prominent, obconic, bud-like stars. It inhabits the Indian ocean, and is snow-white.

PROBLEMATICA. With oblique, minute, immersed, distant stars, and broad punctured margin. Is found about the Antilles islands; it is stony, rough, sea-green, sometimes as thick as a man's arm, and full five feet high; the interstices of the stars are marked with lines.

SPURIA. This is slightly branched and dichotomous, with cylindrical tubes filled with small, irregularly disposed, longitudinal divisions.

INFUNDIBULIFORMIS. This is turbinate, striate, funnel-formed, with slightly prominent stars within. It inhabits the Indian ocean; and is white and solid.

ANGULOSA. Dichotomous, fastigiate, with terminal, turbinate, angular stars, and toothed gills. It inhabits the American seas; is short, thick, cellular, smooth, and white.

DISCOIDES. This species is disk-shaped, somewhat pedunculate, and roughish, with marginal fasciculate stars. It is found in the Indian ocean.

CHALCIDICUM. This is known by its prominent, remote, cylindrical tubes of stars, lamellate without and within. It is found in the Red sea.

CONCAMERATA. This is flat, with remote stars, a little prominent at the margin; the interstices are lamellate. It is found in a fossil state.

ROSACEA. Furnished with a stem, and branched; the lesser branches are cylindrical, ascending; stars terminal; it is sometimes rosy, sometimes white, and sometimes grey.

We shall conclude this article with some general observations, taken chiefly from the 47th volume of the Philosophical Transactions. In speaking of the animal that fills the cavities of the madreporæ, it is said its feet are numerous, and terminate externally in two conical productions, which, being placed on each side of every one of the lamellæ that give the stellular form to the cavity of the coral, serve to affix the animal to the circumference of its cell, and may, with propriety, be considered as the instruments by which the little animal forms the lamellæ themselves. The bases of these conical productions unite and form round bodies, which possess somewhat of the figure, and of the properties of muscles; they serving to lengthen or to shorten the feet, and also most probably to regulate the force with which they clasp the lamellæ, on which they exert their plastic powers. The other ends of these round bodies terminate in small cylindrical tubes, which are attached to the shell of the animal, in the centre of which is seen its head, capable of moving with great quickness, and ornamented with several rays, which

are most probably the arms or claws with which it seizes and secures the animalcules on which it feeds. Admitting that the formation of these corals is the work of the madreporæan polype, it may be thus traced through its wonderful labours. It is found that each of the legs of the polype is provided with two processes, which are applied to each side of one of the perpendicular laminae, while a muscular pyriform body, attached to the other end of the leg, gives to it the power of employing that motion which is necessary for the accomplishment of its task. The young polype may be considered as completing its operation by two distinct processes; the secretion and separation of carbonate of lime from sea-water conveyed through the pyriform body; and its disposition, at the moment of secretion, by the two small processes, where the economy of the animal directs. Proportioned to the number of legs possessed by the infant animal, is probably the number of perpendicular laminae, or pillars, converging in the centre, which it begins to erect; these, when raised to a certain height, appear to be connected together by a horizontal plate of the same substance; on these the animal erects similar pillars, and places on them a covering, similar to that with which he has completed the first compartment. Thus seem to proceed the labours of this minute artist; and as the number of its legs or instruments increase, and as they extend in length, so much the number of the perpendicular laminae, and the circumference of the horizontal plates, augment.

MADREPORE STONE; *Madrepor stein*, Moll. Karsten; *Chaux carbonatée madréporite*, Brongn.

This rare substance, which was discovered by baron Moll in the valley of Rufsbad, in the territory of Salzburg, is considered by some mineralogists as a variety of lime-stone, while Klaproth and others consider it as a distinct species of the calcareous genus.

Externally, and on its longitudinal fracture, its colour is greyish-black; on the cross-fracture, it is of a pitchy black colour.

Has been found hitherto only in massive, blunt-cornered, rounded, and oblong, sometimes flattened pieces, of from three inches to one foot in diameter.

Its surface is more or less finely furrowed, and sometimes small shallow holes are seen in it; furrows often radiating, and marked with transverse minute striæ.

Externally this substance is glimmering, passing into dull; internally, on the longitudinal fracture, partly glimmering, partly glistening; but on the transverse planes of fracture it shews a pitchy lustre, sometimes approaching to metallic. It gives a grey streak.

It is not particularly hard; it is brittle, and easily frangible. Fragments opaque, indeterminate angular, not very sharp-edged, always of a straight or divergingly columnar structure. They often contain copper pyrites, finely disseminated, and in pellicles.

It is not particularly heavy; less so than compact lime-stone.

Before the blowpipe, the black colour of the madreporæ stone is converted into greyish-white.

According to the analysis of Messrs. Schrol and Heim, the constituent parts of this substance are, lime $63\frac{1}{2}$, alumine $10\frac{1}{10}$, silica $12\frac{1}{10}$, iron $15\frac{1}{8}$; and the same constituents, and their proportion, are quoted in the French systems of mineralogy, as the results of an analysis of madreporite made in the *Ecole des Mines*. But Klaproth, who analysed a specimen sent by baron Moll himself, obtained the following results:

Carbonate

Carbonate of lime	-	93.
Carbonate of magnesia	-	0.50
Carbonate of iron	-	1.25
Carbon (radical)	-	0.50
Arenaceous filix	-	4.50
Oxyd of manganefe, a trace	-	—
		99.75

Klapr. Beytr. iii. p. 276.

The structure of the separate pieces of this mineral, resembling the aggregation of madrepores, has given rise to its name. Some mineralogists have, indeed, supposed that the substance derives its origin from a species of madrepores; but Klaproth observes, that this opinion is not supported by any certain mark indicative of preceding organic structure.

Patrin considers the madrepore stone as a fascicular variety of arragonite.

The geognostic situation of this mineral is not known.

MADRET, in *Geography*, a town of Arabia, in the province of Yemen; 10 miles N.E. of Chamir.

MADRID, a city of Spain, in the province of New Castile, and capital of the kingdom; seated on the river Manzanares. The access to its several gates is by streets and avenues, planted with trees; of these, the gate of Alcalá is the most grand, being constructed in the form of a triumphal arch, and the entrance to the city by this gate is the most interesting. As soon as you pass this gate, you are presented with an avenue, having on one side a row of low but uniform houses, and on the other railings, through which are seen extensive gardens; the end of it is crossed by the promenade of the Prado; and the view terminates in the extended street of Alcalá. The origin of this city is not satisfactorily ascertained. Some pretend that it was founded by the Greeks, who never penetrated so far into Spain: others say that it was the ancient Mantua Carpentanorum. It was at first known, however, by the palace, or pleasure-house, possessed here by the kings of Castile; and the foundation of the town is said to have been laid by Alphonso, the 6th of Leon and 1st of Castile, who reigned at the end of the 11th century. We find that it was sacked by the Moors in 1169, and that it was overthrown by an earthquake towards the middle of the 14th century, under the reign of Peter the Cruel, and rebuilt by Henry II., the successor of that prince. Charles I. selected it for the place of his residence, which occasioned its increase from small beginnings, and his son, Philip II., transferred the seat of government to it in 1563. Its first limits were very narrow, and not extended beyond the vicinity of the king's palace; but in process of time it was enlarged by the addition of several suburbs.

Madrid is situated on several low hills near each other, in the midst of an extensive plain, bounded, on the side of old Castile, by the mountains of Guadarama, and undefined by any fixed boundaries on any other side. The plain is dry, parched up, and naked, without trees, and uneven; and the city is situated at a considerable height above the level of the sea. Its situation for the government of the kingdom is convenient, as it lies in the centre of the kingdom, and equally within reach of the distant provinces. Its present extent is 41,333 feet, or two leagues in circumference; its figure is a square; and it has 15 gates of granite, 506 streets, 42 squares, large and small, 7398 houses, 133 churches, convents, colleges, seminaries, or hospitals, 65 public edifices, 17 fountains, and several promenades. It is divided into eight districts, each district into eight wards,

VOL. XXII.

to each of which an alcade is attached, a sort of commissary of police, chosen annually from among the inhabitants. The population, according to the account of 1788, amounted to 156,272 persons; and if the garrison be included, which consists of from 8 to 10,000 foreigners, and Spaniards from the provinces, the population may be reckoned at 200,000. Townsend reckons 13 parishes, 7398 houses, 32,745 families, amounting to a population of 147,543. The number of deaths in 1788 was 5915, and that of the births 4897. In 1797, the deaths were reckoned to be 4441, and the births 4911. The Plaza Mayor, which is near the centre of the city, and from which several streets branch out, is the most populous and best frequented place in Madrid, the centre of commerce, and particularly of retail trade. It is likewise the place where public fêtes are given, and at that time acquires, from its decorations, illuminations, and crowds of spectators, a grand appearance. Madrid is well laid out; and though it has many narrow, and crooked streets, the greater number are handsome, and there are some which would do honour to the finest cities in Europe. That of Alcalá is the most distinguished, as it extends in a straight line from the Prado to the Puerta del Sol, and is broad enough to admit ten carriages abreast; but the houses are not lofty in proportion to the breadth of the street. The streets, though roughly paved, are kept very clean, and well lighted by lamps placed on both sides over the houses, opposite to each other, at equal and short distances. Many of the private edifices, especially in the large streets, though displaying no magnificence of architecture, exhibit an agreeable appearance. The interior of the houses of persons of superior rank is handsomely and magnificently furnished; some of them being adorned with chef-d'œuvres of the fine arts.

The city of Madrid is in the diocese of Toledo; and the spiritual administration is directed by the grand vicar of that city; a bishop *in partibus infidelium*, auxiliary to the archbishop, also resides there, with the powers of that prelate. In Madrid they reckon 15, or, as Townsend says, 13 parishes and six chapels of ease; and a number of monasteries, convents, &c. which it is needless for us to specify. The secular clergy are 395 in number; and the regular clergy, including those of the monks and nuns, amount to 2718; amounting in the whole to 3113. The establishments, under the name of hospitals, and benevolent associations for the relief of indigence and distress in this city, are very numerous. The head of the civil administration of Madrid is a military governor, who bears the honours of captain-general of a province; and the police is under the superintendance of different magistrates. Since the expulsion of the Jesuits, Charles III., in 1770, established an enlarged plan for the instruction of youth, the execution of which is committed to a number of secular priests, who, in one of the houses formerly occupied by the Jesuits, superintend the college of St. Isidore. This establishment includes sixteen masters, or professors, for the languages and sciences, and a good library. There is another college appropriated to the instruction of the young nobility. The academies are numerous: amongst these we may reckon four for jurisprudence, and another for medicine; a Spaniard academy, founded in 1714, by Philip V., for the improvement of the Spanish language; an academy for history, instituted in 1735, by the same prince, for the elucidation of historical subjects, in connection with geography and chronology: the academy St. Fernando, devoted to painting, sculpture, and architecture, which originated in the munificence of Philip V. Amongst the libraries, we may enumerate the royal library, formed in 1712, and containing a

M A D R I D.

great number of printed volumes, a large collection of MSS., a variety of modern medals, and a selection of antiques: the cabinet of natural history was formed by Charles III., and is receiving continual accessions. To the class of curious and useful edifices in Madrid, we may refer several of its churches, its gates, the custom-house, erected in 1769, the house of the academy of St. Fernando, and of the cabinet of natural history, the Casa de Carreos, or post-house, the Caracé de Corfe, or state-prison, erected under Philip IV., the Casa del Ayuntamiento, or town-house, the Palacio de los Confajos, or council-house, which is the seat of a supreme tribunal, the Armeria Real, or royal magazine, and the king's palace. The latter stands on an eminence at one of the extremities of Madrid, commanding a distant view of the beautiful country, which is watered by the Manzanares; founded by Alphon. VI. in the 11th century, sacked by the Moors in 1109; afterwards destroyed by an earthquake. but repaired by Henry II. and completed by Henry IV.; much enlarged by Charles V., and his successors; totally consumed by fire in 1734; and, in 1737, rebuilt on its present plan by Philip V. and Ferdinand VI. This new palace presents four fronts, 470 feet in length, and 100 in height, enriched with numerous pillars and pilasters. The interior of this palace is ornamented by several productions of the arts. Its walls and ceilings are covered with allegorical paintings by the best masters; and the apartments are filled with pictures by the most eminent artists, among which we may select an Adoration of the Magi by Rubens, and a Bearing of the Cross by Raphael. Among the paintings we may also select a piece by Titian, of Venus binding the Eyes of Cupid, an Apotheosis of Hercules by Mengs, and an Adoration of the Shepherds by the same master. There is also a group of nymphs dancing round the statue of Priapus by Pouffin. One of the most magnificent apartments in the palace is the king's hall, in which his majesty gives public audience to foreign ambassadors; it is a double cube of 90 feet, hung with crimson velvet, and adorned with a sumptuous canopy and painted ceiling; it is embellished with mirrors of an extraordinary size, with several antique heads, and a small equestrian statue of Philip II., in gilded bronze. The palace is the depository of the crown jewels and regalia; among which we may mention a superb throne, with its canopy, constructed for Philip II. The Buen-Retiro is another royal mansion, situated in another extremity of Madrid, opening on the promenade of the Prado, and extending to the country that borders on the road from Alcalá to Madrid; erected by Philip IV. This palace is environed by beautiful gardens, which occupy an immense area, in one of which is placed an equestrian statue of Philip II. in bronze. Madrid has several promenades, but their distance renders them inconvenient of access. Of these the Prado is that which is most frequented.

Madrid does not possess one manufacture, from which it can derive any advantage. It has, indeed, three for hats, and another for stained paper, but they are barely sufficient to answer the demands of the capital. There are also three others of greater note, for inlaid work in stone, for tapestry, and for porcelain; but as they are appropriated to the king, they are wholly unproductive to commerce. A considerable manufacture of salt-petre was also established in 1779, and in 1785 it occupied 4000 men, the number of which has since been increasing. Madrid is so destitute of commerce, that it is absolutely dependent for support on remote provinces or foreign countries for every article of use or ornament, for clothes and corn, for all the luxuries and necessaries of life. This city has no discriminating character with regard to manners or customs. Its amusements are numerous; but that

which most interests the inhabitants is the bull-fight. In Madrid are three theatres, which scarcely receive from those who attend them sufficient encouragement for their support. On Corpus Christi day there is a grand procession, composed of the secular and regular clergy of Madrid, followed by the king, his ministers and court, each bearing in his hand a wax taper. As to the climate of Madrid, we observe that the sky is almost always serene and free from clouds; the air is dry, pure, and bracing, especially in the winter season, but it is highly injurious to hectic subjects. The air is so piercing, as to give rise to the proverb, that the air of Madrid destroys a man, when it does not extinguish a candle. The winds most prevalent are, the north in winter, the south and west in spring. In summer the heat is intense, and during the months of July and August almost insupportable. The usual heat in summer is said to be from 75° to 85°; at night the thermometer seldom falls below 70°; the mean height of the barometer is 27°.96. It seems to be about 1900 feet above the level of the sea. Upon the whole, Madrid may be considered as a healthy residence. The various articles of food consumed in this capital are supplied by different parts of Spain. Its bread is excellent, and its water is pure and good. For the supply of the capital, schemes have been adopted for rendering the small stream of Manzanares the channel of communication with the provinces. With this view it has been proposed to form a junction between the Manzanares and the Xarama; and at length under the auspices of Charles III. a canal was formed from the bridge of Toledo near Madrid to the Xarama, near the village of Manzanares, which includes a distance of four leagues. N. lat. 40° 25' 18". W. long. 3° 12'. Laborde's View of Spain, vol. iii. Townsend's Travels in Spain, vols. i. and ii.

MADRID, a town of America, in the northern part of Louisiana, seated on the W. bank of the Mississippi, settled some years ago by Col. Morgan, of New Jersey, under the patronage of the Spanish king, and called by the name of the capital of his European dominions. The spot on which it was proposed by the settlers to found a great city, is situated in N. lat. 36° 30', and 45 miles below the mouth of the Ohio river. Its limits were proposed to extend four miles S. and two W. from the river, so as to cross a beautiful deep lake of clear spring water, called St. Anne's, 100 yards wide, and several miles in length, emptying itself by a constant and rapid narrow stream through the centre of the city. On each side of this lake it was proposed to lay out streets, 100 feet wide, and to continue a road round it of the same breadth. A street, 120 feet wide, was to be formed on the bank of the Mississippi; 12 acres of land were to be preserved in the central part of the city, to be laid out and ornamented for public walks; and other lots of land were destined for other public uses. For the completion of this plan, the country round this spot presents several inducements. It is singularly fertile and productive. The natural growth consists of mulberry, locuit, sassafras, walnut, hickory, oak, ash, logwood, &c. besides grape vines in great abundance. The meadows are fertile in grass, flowering plants, strawberries, and with culture produce good crops of wheat, barley, Indian corn, flax, hemp, and tobacco, and are easily tilled. The climate is favourable to health, and to the production of various kinds of fruits and vegetables. Iron and lead mines and salt springs are plentiful; and the banks of the Mississippi, for many leagues, commencing about 20 miles above the mouth of the Ohio, are a continued chain of lime-stone. A fine tract of high, rich, level land S.W., W., and N.W. of New Madrid, about 25 miles wide, extends quite to the river St. Francis. The situation of New Madrid is excellent-ly

ly adapted to its being rendered the great emporium of the western country.

MADRIDEJOS, a town of Spain, in New Castile; 30 miles S.E. of Toledo.

MADRIER, in the *Military Art*, a thick plank, about 18 inches square, strengthened on one side with a strong band of iron, and a strong iron hook, and having, on the other side, a cavity sufficient to receive the mouth of a petard when charged; with which it is applied against a gate, or other body designed to be broken down. See **PETARD**.

MADRIER also denotes a long and broad plank, used for supporting the earth in mining, carrying on saps, making caponiers, galleries, and the like.

There are also madriers lined with tin, and covered with earth; serving as defences against artificial fires, in lodgements, &c. where there is need of being covered over head.

MADRIGAL, in the modern Italian, Spanish, and French poetry, denotes a little amorous piece, containing a certain number of free unequal verses, not tied either to the scrupulous regularity of a sonnet, or the subtlety of an epigram, but consisting of some tender and delicate, yet simple thought, suitably expressed.

Menage derives the word from *mandra*, which, in Latin and Greek, signifies a sheepfold; imagining it to have been originally a kind of pastoral, or shepherd's song; whence the Italians formed their *madrigale*, and we *madrigal*. Others rather choose to derive the word from *madrugar*; which, in the Spanish, signifies to rise in the morning; the *madrigals* being formerly sung early in the morning, by those who had a mind to serenade their mistresses.

Huet supposes it to be a corruption of *martegaux*, a name given to the inhabitants of a district of Provence, who either invented or excelled in this species of composition. If the origin is deduced from the Spaniards, it may have taken its name from a town in Spain, called *Madrigal*. Others, supposing that its first application was to religious poems addressed to the Virgin, *alla Madre*, derive from thence *madriale*, and *madrigale*.

The madrigal, according to M. le Brun, is an epigram without any thing very brisk and sprightly in its fall, or close: something very tender and gallant is usually the subject of it: and a certain beautiful, noble, yet chaste simplicity, forms its character.

The madrigal is usually looked on as the shortest of all the lesser kinds of poems, except the epigram: it may consist of fewer verses than either the sonnet, or roundelay. There is no other rule regarded in mingling the rhymes and verses of different kinds, but the fancy and convenience of the author. This poem, however, really allows of less licence than many others; whether we regard the rhyme, the measures, or the purity of expression. The term is also applied to a musical composition of three or more parts for different voices, adapted to the words of such poems.

MADRIGAL is likewise a musical term for a vocal composition, seldom in less than four parts. The etymology of this word has been much disputed. But it seems as if its first application had been to short religious lyric poems, or hymns, addressed to the virgin, *alla Madre*; whence *madriale* and *madrigale*; but being afterwards applied to poems on love and gallantry, by the Italians, French, and Spaniards, the original import has been forgotten. Indeed, the words of all the madrigals which we have seen of the 16th century, when they were most in favour, seem to belong to the mother of love and gallantry; *alla madre, della gaia, madre galante, mater laticie*, than to the Virgin, or religious subjects. It never can have meant a morning song, as some

have imagined; the Italians having been long in possession of the term *matinata*, a lover's matins under the windows of his mistress; as they have of *serenata*, an evening song. This species of music seems to have been brought to its highest degree of perfection in Italy, by Luca Marenzio, at the latter end of the 16th century, after which time it soon declined, and lost the favour of the public.

Few Italian composers of eminence produced madrigals after Luca Marenzio, except Stradella, and Alessandro Scarlatti, which are admirable.

MADRIGAL, in *Geography*, a town of Spain, in Old Castile, 27 miles N. of Avila.—Also, a town of Spain, in Old Castile, near Olmedo, on the Adaja; 30 miles S. of Valladolid.—Also, a town of Popayan, in South America; 110 miles S. of Popayan. N. lat. $0^{\circ} 50'$. W. long. $75^{\circ} 45'$.

MADRIGOLO, a town of the duchy of Parma; six miles W. of Parma.

MADRISIO, a town of Italy, in Friuli; 30 miles N. of Venice.

MADROGAN, or **BANANATAPA**, a town of Africa, in the kingdom of Mocaranga, in which is a palace of the king. S. lat. 18° . E. long. $29^{\circ} 30'$.

MADROV, a town of Hindoostan, in Mysore; 18 miles E.N.E. of Seringapatam.

MADRUSAVA, a town of Japan, in the island of Niphon; 36 miles S.E. of Xenday.

MADRUZZO, a town of the Tyrol; 4 miles W.S.W. of Trent.

MADS, in *Agriculture*, a provincial term applied to earth-worms.

MADSJAS, in *Geography*, a town of Arabia, in the province of Oman; 20 miles S.E. of Sohár.

MADUE SEE, a large lake of Hinder Pomerania, drained in 1770, and now inhabited.

MADUGAR, a town of Hindoostan, in the circar of Jyenagur; 10 miles S. of Jyepour.

MADURA, a province of Hindoostan, about 180 miles in length, and 80 in breadth, annexed in 1742 to the dominions of the nabob of Arcot.—Also, the capital of the above-named province, fortified with square towers and parapets, and well furnished with cannon. In 1757, this town was purchased by the British troops for 170,000 rupees. The pagoda of this place is one of the most superb in Hindoostan; 80 miles S.S.W. of Tanjore. N. lat. $9^{\circ} 52'$. E. long. $78^{\circ} 11'$.

MADURA, an island and principality in the East Indian sea, reckoned the sixth empire of Java, though not properly belonging to it, as it is a separate island, divided from Java by a narrow strait. It is about 75 miles in length, and from nine to fifteen in breadth. It is very fertile in rice, for which it is one of the granaries of India; and while Java was in possession of the Dutch (now, *i. e.* 1811, surrendered to the English) it was under the government of a prince, who was the vassal of the Dutch company. Its capital of the same name lies on the S. coast. S. lat. $6^{\circ} 44'$ to $7^{\circ} 15'$. E. long. $112^{\circ} 14'$.

MADZAR, a town of Russia, in the government of Caucasus; 56 miles E.N.E. of Ekaterinograd.

MÆCENAS, **CAIUS CILNIUS**, in *Biography*, an illustrious Roman knight, descended from the kings of Etruria, has rendered himself immortal by his liberal patronage of learned men and of letters, and to his prudence and advice Augustus acknowledged himself indebted for the security which he enjoyed. His love of pleasure removed him from the reach of ambition, and he preferred to die, as he had been born, a Roman knight, to all the honours and dignities which either the friendship of Augustus or his own popula-

rity could heap upon him. He attended the emperor through his various fortunes, and in some military actions he is said to have displayed both valour and skill. He, however, chiefly served his master in a civil capacity, and was one of the three intimates, who were delegated by him to effect an accommodation with Antony when he had laid siege to Brundisium. During a long period he held the important post of prefect of Rome, to which his political talents were peculiarly adapted, and with perfect fidelity to the emperor, and vigilance to maintain his interests, he was not chargeable with any acts of cruelty and oppression. It is to the honour of Augustus that he received the private admonitions of Mæcenas in the same friendly manner in which they were given, and he was not displeas'd with the liberty which he once took of sending to him a paper with these words written upon it, "furge carnifex," "rise butcher," while he was sitting on his judgment seat, and betraying revenge and impatience in his countenance. He was struck with the admonition, and left the tribunal without passing sentence of death on the criminals. No minister was more the personal friend of his sovereign than Mæcenas; for this it is thought he was partly indebted to the attachment of the emperor to his wife Terentia, at which the favourite disgracefully connived. It is said that a coolness took place in his latter years between him and the emperor, but at his death, which happened about the eighth year before the birth of Christ, he instituted him his general heir. Though a zealous patron of learning and learned men, he was a man addicted to the pursuit of pleasure. "Where vigilance was required," says Velleius Paterculus, "he was sleepless, provident, and active, but as soon as a relaxation from business could be permitted, he dissolved in a more than feminine indolence and delicacy." The style of his own compositions was infected with the same effeminacy which characterized his manners, but the soundness of his judgment with respect to the writings of others, seems apparent from the merit of those on whom he bestowed his patronage. His name is perpetuated by the two great Roman poets, Virgil and Horace: with the latter he lived upon a footing of freedom and familiarity, which does equal honour to both, and no name appears with so much distinction in his works as that of Mæcenas. Virgil dedicated to him his *Georgics*, which appear to have been composed at his request. So signal were his good offices towards literary genius, that the name of Mæcenas has ever since been applied to its liberal patrons. Of his own writings a single specimen only has come down to our times, the sense of which is, that he would be contented to live, though oppressed by almost any bodily sufferings and infirmities that could be accumulated, a sentiment which a Roman philosopher would despise, but which has been avowed by persons of our day, whose names will be perpetuated to distant ages by the works which they have left behind them: among these may be mentioned the celebrated Dr. Johnson, and the author of the *ΕΤΕΡΑ ΠΙΣΤΟΙΣΙΝ*; the one from a dread of death, the other from an attachment to life: the latter, indeed, enduring much bodily pain, and very great infirmities for many years, in the midst of them all, never ceased to wish for a prolongation of life, nor to express a lively sense of the obligations he was under for a large balance of happiness in his favour; and on the tomb, intended by himself for his lifeless body, he inscribed, while living, the expressive epitaph, "Contented and Grateful." The historian Dio has attributed to Mæcenas the introduction of warm baths at Rome, and also the invention of a species of short-hand writing, by the aid of which orations could be taken down from the mouth of the speaker: other writers, however, ascribe this to Cicero's freedman Tiro. He is supposed to have been the author of a history of ani-

mals; a journal of the life of Augustus; a treatise on the different natures and kinds of precious stones, besides the two tragedies of Octavia and Prometheus, and other things that are lost. Univer. Hist.

MAEGOA, or **FREMONA**, in *Geography*, a town of Abyssinia; 9 miles from Axum.

MAEL-CARHAIX, a town of France, in the department of the Northern Coasts, and chief place of a canton, in the district of Guingamp. The place contains 1767, and the canton 7395 inhabitants, on a territory of 225 kilometres, in eight communes.

MAEL *Coronde*, in the *Language of the Celonese*, the flowering cinnamon-tree. This is a name given to a peculiar species of the cinnamon-tree, which is all the year round found full of flowers. The flowers are not easily to be distinguished from the very finest cinnamon-flowers, but they produce no fruit, which the flowers of the fine cinnamon always do. The bark is much like that of the best cinnamon, in external appearance; but it has very little taste or smell. The tree grows very large, and the inhabitants sometimes tap it, by boring a hole in the trunk, at which it bleeds a thin watery juice, in the manner of our birch-tree.

MÆANDER, in *Geography*, a river of Turkey, in Asia, which rises N. of the ancient city of Apamea, and runs in a winding stream, about 250 British miles, and not far from its mouth, is about 190 feet broad. It is called by the Turks Boone Minder, or Great Mæander, to distinguish it from another little stream, which resembles it in its course.

MÆATÆ, in *Ancient Geography*, a general name, which comprehended the following five British nations, *viz.* the Otodeni, Gadeni, Selgovæ, Nevantæ, and Dumni, who possessed the country between the walls of Severus and Antoninus Pius. This name, used by the Greek and Roman writers, was probably not unknown to the Britons themselves; and is supposed by some to have been derived from two British words, *moi*, a plain, and *aitich*, inhabitants, and by others from *mean*, middle, and *aitich*, as being situated in the middle, between the provincial and unconquered Britons. We have sufficient evidence, that the Roman armies, under Julius Agricola and the emperor Severus, penetrated a considerable way into that part of Britain which lies to the N. of the wall of Antoninus Pius, between the firths of Forth and Clyde. Tacitus (*Vit. Agric. c. 21 to 39.*) gives a very distinct account of the first of these famous expeditions in Caledonia, and Dio Nicæus of the second. (*Xiphilin. e Dione in Sever.*) Many Roman coins have been found in several parts of that country, and there are still remaining in it very distinct vestiges of several Roman camps. But it is no less evident, that the Romans never formed any solid or permanent establishment beyond the wall of Antoninus, which was always considered as the utmost limit of the Roman empire in Britain.

MÆLER, in *Geography*, a very beautiful lake of Sweden, containing several islands rich in wood and pasture, with hilly shores, diversified with trees, villas, and farm-houses. It is usually frozen in winter, and opens an easy communication, by means of sledges, with Stockholm. See **ARBOGA**, **CANAL**, and **TROLHÆTTA**.

MAELLA, a town of Spain, in Aragon; 15 miles E. of Alcaniz.

MAELSTROM, a whirlpool in the North sea, near the island of Moskoe. Its noise is heard at the distance of several leagues, and it is so violent, that a vessel which comes near it is drawn irresistibly into the vortex, and carried immediately to the bottom, where it is dashed to pieces against the rocks. At flood tide the stream runs up into the country with a boisterous rapidity; and at ebb, it returns to the sea

with a violence and noise not equalled by the loudest cataclysms. Whatever it carries down, it instantly absorbs; but at the turn of ebb and flood, when the water becomes still, the scattered fragments rise to the surface. When this whirlpool has been agitated by a storm, it reaches vessels to the distance of five or six English miles, at a time when the crews have thought themselves perfectly secure. N. lat. $67^{\circ} 40'$. E. long. $11^{\circ} 44'$.

MÆMACTERION, Μαμακτεριον, in *Chronology*, the fourth month of the Athenian year. It contained twenty-nine days, and answered to the latter part of our September and beginning of October. The Bœotians called it *alcalomenius*.

It took its name from the festival Memaçteria, sacred to Jupiter, kept at this time.

MÆMACYLON, in the *Materia Medica*, a name given by Dioscorides, and the ancients in general, to the fruit of the *arbutus*, or strawberry-tree.

MÆNA, in *Ichthyology*, the name of a small fish, caught in vast abundance about the shores of the Mediterranean, and common in the markets of Italy, where they are accounted but a poor sort of fish, and sold at a very cheap rate. It is somewhat of the figure of the perch, but broader and thinner, and is seldom above four or five inches in length.

MÆNA Candida, a name given by many authors to the smaris. It is not very improper, for they are both of the same genus of the sparus, and are very nearly allied to one another; the principal difference consisting in the tail and belly fins of the smaris being red. See **SPARUS**.

MÆNALUS, in *Ancient Geography*, a mountain of the Peloponnesus, in Arcadia, mentioned by Strabo, Pliny, and Virgil. This mountain was particularly consecrated to Pan. Several towns were situated on the extent of this, which were destroyed, and whose inhabitants assembled at Megalopolis.

MÆONIA, a country of Asia Minor, formerly comprehending that part of Lydia which lay eastward towards mount Tmolus, and which was the source of the Pactolus.—Also, a town of this province, situated at the foot of mount Tmolus.

MÆOTÆ, a Scythian people who inhabited the banks of the Palus Mæotis, and who gave their name to this lake.

MÆOTIS, or **MÆOTIS Palus**. See *Sea of AZOF*.

MAERHUET, in *Geography*, a town of Sweden, in Smaland; 31 miles N.W. of Calmar.

MAERNA, a town of the Tyrol; 23 miles W.S.W. of Trent.

MAERSE, a town of Holland, in the department of Utrecht; 5 miles N.W. of Utrecht.

MÆRUA, in *Botany*, so called by Forskäll from its Arabic name *Meru*, is one of his genera, adopted by Jussieu, Vahl and Willdenow.—Vahl Symb. p. 1. 36. Willd. v. 2. 1168. Juss. 440. Class and order, *Polyandria Monogynia*. Nat. Ord. *Plantæ incertæ sedis*, Juss.

Gen. Ch. *Cal.* Perianth of one leaf, tubular, coriaceous, four-cleft; tube square, short, broader upwards; segments of the limb oblong, obtuse, reflexed, a little longer than the tube. *Cor.* none. *Nectary* at the mouth of the tube of the calyx, entire or divided, shorter than the calyx, conniving, covering the stalk of the germen. *Stam.* Filaments numerous, at the base of the germen, thread-shaped, twice as long as the calyx; anthers oblong, incumbent. *Pist.* Germen cylindrical, shorter than the filaments, smooth, on a thread-shaped, square stalk, the length of the tube,

swelling upwards; style none; stigma obtuse. *Peric.* and *Seeds* unknown.

Eff. Ch. Calyx four-cleft, with the nectary in its tube. Corolla none. Stigma sessile.

Obf. This genus is closely akin to *Grewia*, as Vahl observes, but differs sufficiently from that in having a four-cleft calyx, a nectary crowning the mouth of the tube, and a sessile stigma.

1. *M. uniflora*. Vahl and Willd. (*M. crassifolia*; Forsk. Defscr. 104.)—Stalks single-flowered. Nectary many-cleft. A native of Arabia Felix.—This *shrub* is furnished with round, spreading, very smooth *branches*, and a purplish *bark*; *Leaves* alternate, on footstalks, scattered, often many from the same bud, oval, entire, pointed, thick. *Flowers* axillary, each placed on a solitary, thread-shaped stalk, twice as long as the leaves. *Nectary* divided into many thread-shaped segments.

2. *M. racemosa*. Vahl and Willd.—Flowers racemose. Nectary undivided.—Also a native of Arabia Felix.—*Branches* round and smooth. *Leaves* on footstalks, remote, pendent, oval, pointed, reflexed, entire, smooth, half an inch long; footstalk shorter than the leaf. *Clusters* of flowers terminal, drooping. *Nectary* undivided.

MAES, GODFREY, in *Biography*. Amidst those who practised the art of painting in the Flemish school, after the astonishing powers of Rubens were developed, this artist held a considerable rank. He was born at Antwerp in 1660, and having received early instructions from his father, he improved and perfected himself by studying and copying the fine pictures placed in the great churches and cabinets of his native city.

His works, when he began to practise upon his own invention, were highly approved; and he was much employed both publicly and privately, till at last he was appointed to the distinguished station of director of the academy at Antwerp.

MÆSA, in *Botany*, so called by Forskäll, and by him alone; all succeeding authors having agreed that the plant in question is not generically distinct from **ΒΛΕΒΟΥΡΥΣ**, (see that article)—Willdenow, Vahl and Martyn call the *Mæsa* of Forskäll *B. lanceolata*.—Jussieu suggests the affinity of this genus to Thunberg's *Aucuba*.

MAESEYK, in *Geography*, a town of France, in the department of the Lower Meuse, seated on the Meuse; 30 miles N.N.E. of Liege. N. lat. $51^{\circ} 4'$. E. long. $5^{\circ} 47'$.

MAESLAND, or **MAESLAND SLUYS**, a town of Holland, on a canal that forms a communication between Delft and the Meuse; the inhabitants of which are principally occupied in the herring and whale fishery; 7 miles S. of Delft.

MÆSTLINUS, MICHAEL, in *Biography*, a German astronomer, was born in the duchy of Wirtemberg, and became mathematical professor at Tubingen, where he died in 1590, at the age of forty-eight, leaving behind him several works on mathematics and astrology. In early youth he made a speech in favour of Copernicus's system, which is said to have brought the afterwards celebrated Galileo over from the philosophy of Aristotle and Ptolemy, to whose systems he had been previously devoted. Kepler was one of the pupils of Mæstlinus, and has, in his own work entitled "*Aitronomia Optica*," commended several of his inventions. Martin. Biog. Phil.

MAESTOSO, in the *Italian Music*, majestic, spirited, but not quick.

MAESTRICHT, in *Geography*, a town of France, and principal place of a district, in the department of the Lower Meuse;

Meuse; formerly one of the largest, as well as the most ancient towns in the Netherlands, and belonging to the duchy of Lorraine. The possession of it was secured by Charles V. in 1530, at the diet of Augsburg; and he united it to the duchy of Brabant. Its magistracy is composed of two burgo-masters, one a Catholic, the other a Protestant, and 20 ecchevins, half Catholics and half Protestants. It was formerly a bishop's see; but the see was removed in 710, by St. Hubert to Liege. It has two collegiate, and several parish churches, and before the revolution it had several religious houses: its town-house is handsome, and it has a good library. It has been fortified at different times by the Spaniards, Dutch, to whom it was ceded by the peace of Nimwegen in 1678, and French, when they had respectively possession of it.

The ramparts of Maastricht consist of the old inclosure, flanked with small towers and ancient bastions. But the principal strength of the place lies in several detached bastions, some great, some small, in several horn-works, and a covert-place, in some places double, and in others treble, the whole supported by a vast number of mines. They can form two inundations round the town, to prevent its being approached, one above, the other below the city; besides, on the south side of the town, towards Liege, there is a very strong entrenchment on the declivity of a hill, called fort St. Pierre, able to hold 13 or 14,000 men, which, with the help of several redoubts well planted with artillery, are capable of being a great obstruction to an army that would undertake the siege of the town. This fort consists of a large bastion with a very good casemate, a counterscarp, and two covert-ways; the whole supported with entrenchments which extend right and left to the inundation formed by the little river Jeker. The suburb of Wyck has a rampart a quarter of a league in circumference, flanked with three large bastions, joining to the body of the place. It has likewise another inclosure of earth, flanked with several bastions, ravelins, and a good covert-way. There are likewise two isles, one above, and the other below the bridge, which are strongly entrenched and defended with redoubts and other works. In short, Maastricht is justly looked upon as one of the strongest places in Europe. Near it are large stone quarries, in which are subterraneous passages of great extent, where the farmers frequently store hay, corn, and other articles.

On the 23d of February 1793, it was bombarded by the French, under general Miranda; but being attacked by general Clairfayt on the 1st of March, the republicans lost 2000 men, and nine pieces of artillery, and were compelled to raise the siege. On the fourth of November, the city was taken by the French, the garrison, consisting of between seven and eight thousand men, surrendering themselves prisoners of war. The town contains 17,903, and its two cantons 29,245 inhabitants, on a territory of 120 kilometres, in 22 communes; 15 miles N. of Liege. N. lat. 50° 48'. E. long. 5° 43'.

MAESTRO, a town of Italy, in the Paduan territory; 8 miles N.W. of Venice.

MAESTRO, a master; as *Maestro di cappella*, the master of a choir, or the composer in a cathedral. It is likewise a title given, by courtesy, to the composer of an opera, the master who presides at a harpsichord in a concert, and sometimes to a mere music master.

MAESWINES BAY, in *Geography*, a harbour of Ireland, in the county of Donegal, being one of the many inlets in the bay of Donegal. It lies W. of St. John's Point and E. of the harbour of Killybegs.

MAEVA, a town of Russia, in the government of Irkutsk, on the Lena; 20 miles N.N.W. of Vercholenk.

MAFAMEDE, a small island in the Indian sea, near the coast of Africa. S. lat. 16° 20'.

MAFARECK, a town of Egypt; 30 miles N.E. of Kous.

MAFFÆUS, VEGIO, in *Biography*, a Latin poet, was born at Lodi, in the Milanese, in the year 1407. He was educated for the law, but soon shewed an attachment to the belles lettres, and in future life had the happy art of blending the charms of poetry with the gravity of jurisprudence. He obtained the professorship of the law at Pavia, from whence he was called to Rome, where he held some considerable offices at the church of St. John de Lateran. He died in 1458: his chief works are, 1st, "De Educatione Liberorum," and, 2dly, "Poetical Pieces," of which the most remarkable was a poem called a continuation of the Æneid of Virgil, which has been translated into English burlesque by Mr. John Ellis.

MAFFÆUS, BERNARDIN, a learned cardinal, who died at Rome, at the age of 40, about the year 1553. He is known as the commentator on Cicero's epistles, and as the author of a treatise on medals and inscriptions. Moreri.

MAFFÆUS, or MAFFEI, JOHN PETER, was born at Bergamo in 1536, and was instructed by his uncles Basil and Chrysofom Zanchi, nobles of that city, in the ancient languages, and in philosophy and theology. In 1563 he was appointed professor of eloquence at Genoa, with an ample salary. During the two years which he continued in that office he acquired great applause, and was chosen to the office of secretary of state; in 1565, he returned to Rome, where he entered into the society of Jesuits. He spent six years as professor of eloquence in the Roman college, during which he translated, into the Latin language, the history of the Indies by Acosta, which was published in 1570: after this he was invited to Lisbon by cardinal Henry, to draw up, from papers and other documents with which he was to be furnished, a complete history of the Portuguese conquests in the Indies, and of the progress of the Christian religion in those countries. He returned to Italy in 1581, and spent several years, partly at Rome and partly at Sienna, in learned labours, and at length was placed, by Clement VIII. in the Vatican, for the purpose of continuing, in the Latin language, the annals of Gregory XIII. begun by him in the Italian. He died at Tivoli in October 1603. He wrote the life of Ignatius Loyola, but his principal work is entitled "Historiarum Indicarum, Lib. xvi." which has been frequently reprinted. The best edition is in two volumes 4to. printed at Bergamo in 1747. His works are chiefly to be regarded on account of the purity of the style in which they are written. Moreri.

MAFFÆUS, FRANCIS-SCIPIO, an Italian marquis, and elegant writer in his native language, was born at Verona in 1675. His early education was entirely conducted by his mother, a woman of very superior accomplishments, but as soon as he was of a proper age, he was sent to the Jesuits' college at Parma, where he distinguished himself by his attachment to poetry. Having completed his studies, he visited Milan, Genoa, and Rome, and at the last named city he was admitted into the Academy degli Arcadi. He now devoted himself to the pursuits of polite literature. Uniting the spirit of philosophy with that of gallantry, he maintained, before an assembly of both sexes in the academy of Verona, certain "Conclusioni d'Amore," in which the elegance of his language and the vivacity of his sentiments were equally admired. For a short time he quitted the arts of peace and joined

joined the army, in which he served as a volunteer at the battle of Donawert in 1704, under the command of his second brother, who was general of the Bavarian troops in alliance with France: during the campaign he had an opportunity of saving his brother's life, by disarming an officer whose pistol was pointed at him. At the conclusion of the campaign he returned to Verona, and resumed those literary occupations which he never after forsook. He set himself to reform the stage, and produced, by way of model, his tragedy of "Merope." About the same time he undertook the more important task of reforming the moral principles of his countrymen, especially with regard to the practice of duelling, to which his brother had nearly fallen a sacrifice. On this subject he published two works, of which the latter, entitled "Della scienza chiamata cavalleresca," he dedicated to pope Clement XI. This was a performance of much learned research and solid argument, and so well written in every respect, that it acquired general applause, and passed through several editions. His "Merope," already noticed, was exceedingly popular, and was translated into most of the modern languages. By some of his contemporaries it was severely criticised and violently censured: among these was Voltaire, who afterwards attempted to rival it by a tragedy of the same name, which is reckoned one of his best pieces. Maffæus soon after wrote a comedy, entitled "Commedia delle Cerimonie;" and a drama, called "La Fida Ninfà." He was indefatigable in his studies of antiquity and theology, with the view of promoting the honour of his native country, and the spreading of the Roman Catholic religion. One of his most useful works on the subject of antiquities was his "Istoria Diplomatica," being an introduction to the critical knowledge of pieces distinguished under the name of diplomas, with a collection of several documents hitherto inedited. In 1732 he raised a durable monument to the fame of his native city, by a learned work, entitled "Verona Illustrata." This piece is comprised in four parts, and is replete with curious information relative to the history and antiquities of the north of Italy, and ranks among the ablest and most interesting of topographical works. His principal object in a tour undertaken through foreign countries, was the collection of ancient inscriptions, with the design of uniting them with those collected by Gruter, and other writers on the same subject. In his journey he visited every place where the relics of antiquity and the cabinets of the curious were to be found. On his arrival at Paris, he printed an account of what he had seen under the title of "Galliæ Antiquitates quædam selectæ." Here he was elected a foreign member of the Academy of Inscriptions, and was a frequent attendant on its meetings. The disputes concerning the bull Unigenitus interested him so warmly, that he studied the subjects in dispute with the utmost zeal, and in a short time produced an elaborate folio volume, the result of his theological reading. In this he appeared as the champion of the Molinists against the Jansenists, and the defender of the bull Unigenitus. This was not published till the year 1742, and previously to it he passed from Paris to London, where he was distinguished by the notice of the royal family, several of the nobility, and by the most eminent men of letters. He visited both universities, and received at Oxford, in compliment to his literary merit, the degree of doctor of laws. From England he went to Holland and Flanders, and proceeded through Germany to Vienna, where he had a most gracious reception from the emperor Charles VI. He returned to Verona in 1736, and immediately began to publish the "Osservazioni Letterarie," intended as a continuation of the Italian literary journal. Several original pieces of Maffæus, relative to his history and

antiquities, appeared in the successive tomes of his works. The true members of the church of Rome having maintained, in opposition to the Jesuits, that taking interest of money to any degree was the crime of usury, Maffæus opposed this doctrine in a work entitled "Dell' Impiego del Danaro," which was a learned and rational dissertation on the employment of money in ancient times, and the true principles of morality and policy on this head. For this treatise he incurred the charge of heresy, and was banished the city: the storm at length passed over, and he returned in triumph. After this he published many other pieces on various topics; among these was a metrical version of the two books of the Iliad; some Hebrew poetry; and enquiries into the generation of lightning and other physical phenomena in nature. Ever actuated by a desire of advancing the glory of his native city, in which he had already promoted the liberal studies, by transplanting a colony of learned teachers from the Arcadi at Rome, and establishing a literary assembly in his own house, he exerted himself in laying the foundation of a museum of antiquities and curiosities, which became considerable, and was announced to the public by a catalogue entitled "Museo Veronese." In 1749 he endeavoured to correct the popular notions concerning magic and witchcraft, by a treatise, "Arte magica dileguata," which brought upon him a host of enemies, of whom fourteen replied to his reasonings. He was not, however, to be intimidated, and justified himself by the publication of two other pamphlets on the same subject. His next work was entitled "De' Teatri Antichi e Moderni," in which he attempted a vindication of theatrical spectacles, in opposition to those who maintained that they were all unlawful. He continued to devise new plans, to augment and confirm his literary reputation till the year 1754, when the effects of old age and the severity of winter threatened him with immediate dissolution. As soon as his danger was known in the city, the council ordered public prayers to be put up for him during three days. His valuable life was protracted a few weeks only, and on the 11th of February 1755, he expired, in the 79th year of his age. He was interred amidst a vast concourse of mourning fellow citizens, and a statue was erected to his memory in the principal square, by the side of those of Fracastoro, and others who had conferred honour on Verona. Gen. Biog.

MAFFAH, *Old and New*, in *Geography*, two towns of the island of Madagascar; the first situated on the N.W. coast, in S. lat. 15° 22'. E. long. 51°; and the second, 25 miles S.E. of the other.

MAFFERSDORF, a town of Bohemia, in the circle of Boleflaw; 10 miles N. of Turnau.

MAFFRA, a town of Portugal, in the province of Estramadura, containing about 1040 inhabitants; near which king John V. erected a magnificent building; in consequence of a vow, made in a dangerous fit of illness, to found a convent for the use of the poorest priory in the kingdom, which was found to be that of Maffra. The building was designed to exceed even the Escorial; it is constructed of white marble, contains 37 windows in front, and is nearly a square of 728 feet; in the centre is the church, with the palace on one side and the convent on the other. This structure was commenced by order of king John V. in 1717, and finished in 1742, the architect being a German, named John Frederic. In the whole building, it is said, there are 870 rooms, and 5200 windows; five miles N.W. of Lisbon.

MAFMALA, a small island in the Indian sea, near the coast of Africa. S. lat. 16° 20'.

MAFORTIUM, among the *Romans*, a veil or head-dress worn by the married women.

MAFRAGG, in *Geography*, a river of Africa, in Algiers, which

which runs into the Mediterranean, near Cape Rofa; anciently called "Rubricalus."

MAFUMO, or **ENGLISH RIVER**, a river of Africa, which runs into Delagoa bay, navigable for large vessels; its channel is about a mile wide; and ships lie commonly about two miles up the river, where, in good depth of water, they are safe from all winds and supplied plentifully with provisions, such as beef, goats, fowls, fish, lemons, oranges, sweet potatoes, and other vegetables, with good water on both sides of the river. S. lat. 26°.

MAGACELA, a town of Spain, in Estramadura; 18 miles E.S.E. of Merida.

MAGADA, in *Mythology*, a title under which Venus was known and worshipped in Lower Saxony; where this goddess had a famous temple, which was treated with respect even by the Huns and Vandals, when they ravaged the country. It is said to have been destroyed by Charlemagne.

MAGADINO, in *Geography*, a town of Italy, in the bailiwick of Locarno, on the lake of that name; five miles S. of Belinzona.

MAGADIS, **MAGAS**, from *μαγαδίζειν*, to sing, or play in unison or octave, the name of a musical instrument in use among the ancients.

There were two kinds of magades, the one a stringed instrument, formed of twenty chords, arranged in pairs, and tuned to unison or octave, so that they yielded ten sounds; the invention of which is ascribed by some to Sappho; by others to the Lydians; and by some to Timotheus of Miletus.

The other was a kind of flute, which, at the same time, yielded very high and very low notes. The former kind was, at least, much improved by Timotheus of Miletus, who is said to have been impeached of a crime, because, by increasing the number of chords, he spoiled and discredited the ancient music.

Among all obscure terms in the ancient Greek music, which have bewildered modern inquirers, few have perplexed them more than this, and its meaning is still so far from settled, that we have yet to learn whether it was a wind or a stringed instrument; or, indeed, whether it was any instrument at all, or any thing more than a monochord, or the bridge of an instrument. Rousseau assures us, that the verb, *to magadize*, in the Greek music, implied to sing in the octaves, as a man and a woman, or a boy, naturally do; and adds, that as the word comes from *magas*, the bridge of an instrument, by extension it was applied to an instrument with double strings tuned octaves to each other, like the unisons and octave in our old double harpichord.

MAGADOXO, **MAGADOSHØ**, or *Maldoscho*, in *Geography*, a kingdom of Africa, situated along the coast of the Indian sea, from the river Jubo, near the equinoctial line, to beyond the fifth degree of north latitude. Its name is derived from its capital, which is situated in a large bay, formed by the mouth of a river of the same name, called by the Arabs, "the Nile of Magadoxo," on account of its annual overflowing. The source of this river is not ascertained, but its course is concluded to be long, from its considerable channel and large bay, and also from its extensive inundations, which supply various canals, and fertilize the country through which it runs, so that it produces in abundance wheat and barley, and a variety of fruits, and supplies food for numbers of horses, oxen, sheep, and other animals which are bred near its banks. The city of Magadoxo is a place of great commerce, and vast resort from Aden and other parts; whence their merchants bring cotton, silk, and other cloths, spices, and drugs, which they exchange with the inhabitants

for gold, ivory, wax, and other commodities. The inhabitants are chiefly Mahometans, among whom are many Bedouin Arabs, who retain their ancient superstitions, and farther inland there is a greater number of Abyssinian Christians, subject or tributary to that empire. The king and his court are Mahometans; his subjects, of whom some are white, others tawny and olive, and others black, all speak the Arabic tongue. They are stout and warlike, and use, among others, poisoned arrows and lances. The town is situated in N. lat. 2° 6'. E. long. 45° 50'.

MAGALAWAUK, a town of Hindoostan, in Mysore; 10 miles W.S.W. of Punganore.

MAGALHAENS, **Ferdinand de**, in *Biography*, commonly known by the name of Magellan, an eminent navigator, was by birth a Portuguese. He served with much reputation during five years under Albuquerque, in the East Indies, and particularly distinguished himself at the conquest of Malacca in the year 1510. After this, thinking his services had been but miserably requited by his own court, he entered into the employment of Charles V. king of Spain, who gave him the command of a fleet, with which, in 1519, he discovered the straits called after himself at the extremity of South America. Soon after this he took possession of the Ladrones and Philippine islands in the name of the monarch in whose service he was engaged. At one of the latter, named Zebu, Magalhaens obtained the conversion of the king, having assured him that by becoming a Christian he would be rendered superior to his enemies. Under the farther condition of his becoming a vassal to Spain, the Portuguese assisted him in his attempts to reduce to subjection the neighbouring chieftains, and the holy cross was erected over the smoking ashes of some villages that had been plundered and destroyed. In one instance his authority was set at nought, and he determined to inflict a summary vengeance on the rebellious chief: he accordingly landed with about fifty of his men upon the island of Matan, and was met by the chief and his people, who though rudely armed, and subject to no regular discipline, made a formidable resistance during the greater part of a day. At length the fire of the Spaniards slackened from want of ammunition, and the islanders pressing on, a retreat became necessary. Magalhaens received a wound from an arrow in the leg, and being ill supported by his men, he was beaten down and slain by a lance. This happened in 1521, and by this act of imprudence he lost the honour of being the first circumnavigator of the globe. He has, however, secured to himself a high reputation among maritime discoverers, by the commencement of this great enterprize. Barney's Discovery in the South Sea.

MAGALOTTI, **Count Lawrence**, a celebrated philosopher and mathematician, was born at Rome in 1637. Having been initiated in the elements of learning, he was sent to the university of Pisa, for the purpose of studying jurisprudence, in which he made a great and very rapid progress, but the bent of his genius led him to devote his main attention to the study of mathematics and natural philosophy. He cultivated these branches of science at Florence, during three years, under the celebrated Vincent Viviani, and was, by his recommendation, and that of Borelli, made secretary to the Academy del Cimento, which had been established, in 1656, by prince Leopold of Tuscany, for the express purpose of elucidating philosophical science by a series of experiments. The duties of this appointment Magalotti discharged with the utmost assiduity and care, and being directed by the prince to draw up an account of the experiments made there, he aimed at rendering his work popular, as well from its elegance as from

from the perspicuity of its style. The work was accordingly published in the year 1666, and was received with universal applause by men of science. The subjects which it embraces are the pressure of the air; natural and artificial freezing; the various effects of heat and cold; the compression of water; magnetism; the nature of colours; of sounds; the projection of bodies, &c. While the secretary was engaged in drawing up his account of the experiments of the academy, he obtained leave from Leopold to pay a visit to his father at Rome, where he wished to consult the learned Angelo Rici on the subject of that work; but the chief object of his journey was to obtain some ecclesiastical promotion. Having failed in this object, he determined to return to Florence, and to apply for a place at the court of the grand duke Ferdinand II. In this he was successful; and shortly after a pension was given him by pope Alexander VII., to whom prince Leopold had presented a considerable part of the instruments used in making the experiments at the academy. He attempted a work on electricity, but the science was too much in its infancy, and the facts known respecting it were too scanty to admit of much being done in it. While engaged in these pursuits he did not neglect his favourite study astronomy, and at the same time paid some attention to theology, particularly to the writings of the fathers. About the year 1666, he drew up and published a small volume relative to the history and peculiarities of China, which was received with great applause; and at the same time he published a small, but elegant Compendium of the Moral Doctrine of Confucius. He was a good poet, and the first person who published a good translation of the Odes of Anacreon in Italian verse. He was very conversant in many of the modern languages, and could write and speak French, Spanish, and English, with the correctness and ease of the natives of those countries. Of this he gave abundant evidence in different visits which he paid to them either in a private or official character. In England he was the intimate friend and bosom companion of the illustrious Mr. Robert Boyle, whom he attempted to convert from the errors of the Protestant faith, but the English philosopher was too well grounded in the evidences of his religion to be moved by the eloquence of his Catholic friend. He was employed in several missions to foreign princes, and at length, in 1674, he was appointed ambassador to the imperial court. At Vienna he was received in the most honourable manner by persons of all ranks, and acquired the particular favour of the emperor. Here he formed an intimate connection with the men most eminent for science and literature, and spent his time agreeably in learned leisure, till he was embarrassed by the delay of the necessary pecuniary remittances from his court. He now determined to return to Florence without waiting the permission of the duke. Shortly after, that prince superseded him in his embassy to Vienna, and gave him apartments in his palace, with a considerable pension. This was not exactly the thing which he wished, and which his services seem to have claimed; he therefore withdrew into retirement, and gave himself up entirely to his studies. In 1684, he composed fifteen Italian odes, in which he has drawn the picture of a woman of noble birth, and exquisite beauty, distinguished not only by every personal, but by every mental charm, and yet rendering herself chiefly the object of admiration and delight by her manners and conduct. Not believing that such an original existed in nature, he gave this piece the title of "The Imaginary Lady." His next work consisted of Letters against Atheists, in which his learning and philosophy appear to great advantage. In the year 1689, he

was appointed a counsellor of state to the grand duke, who sent him his ambassador into Spain to negotiate a marriage between one of his daughters and king Charles II. Soon after he had accomplished the object of this mission he sunk into a temporary melancholy, which led him to exclude himself from all intercourse with the world for nearly a year, till by the intreaties of the grand duke he was induced to return to his post at court. He now resumed very successfully his literary labours, and published works upon various subjects, and left others which were given to the world after his decease, which happened in the year 1712, when he had attained the age of 75. Magalotti was as eminent for his piety as he was for his literary talents; unimpeachable in his morals, liberal, beneficent, friendly, polite, and a lively and cheerful, as well as very instructive companion. His house was the constant resort of men of letters from all countries, whom he treated with elegant hospitality. He was deeply conversant with the writings of the ancient philosophers, and was a follower of the Platonic doctrine in his poems. In his natural and philosophical investigations he discarded all authority, and submitted to no other guide but experiment. Among the moderns he was particularly attached to Galileo. After his death a medal was struck in honour of his memory, with the figure of Apollo raised on the reverse, and the inscription OMNIA Lustrat. In the General Biography is given a long list of his various publications, taken from the third vol. of the well known work entitled "Fabronii Vit. Italorum doct. excell."

MAGAME, in *Geography*, a town of the island of Ceylon, near the E. coast; 96 miles S.E. of Candy.

MAGAN, a town of Spain, in New Castile; 8 miles N.N.E. of Toledo.

MAGANJA, a river of Africa, which runs into the Zambeze, S. lat. 16° 20'. E. long. 33° 40'.

MAGAPERAM, a town of Hindoostan, in the circuit of Cuddapa; 14 miles N.N.E. of Combam.

MAGARABA, a mountain of Africa, in Algiers, extending about 30 miles along the coast of the Mediterranean, inhabited by a people called "Magarabas," descended from the Berberes, who live in tents, feed large flocks, and pay a tribute to the dey of Algiers.

MAGARZAN, an island in the Red sea, near the coast of Nubia; it is high, and the largest of three forming a triangle, about five miles in length. N. lat. 21° 10'.

MAGAS, in the *Ancient Music*, is used to denote the bridge of any instrument. See MAGADIS.

MAGASSA, in *Geography*, a town of Tyrol; 24 miles W.S.W. of Trent.

MAGATTI, CÆSAR, in *Biography*, (or, as he was called in his Latin writings, *Magatus*), an eminent surgeon, was the son of a respectable citizen of Scandiano, in the duchy of Reggio, where he was born in 1579. He distinguished himself by his early proficiency in philosophy and medicine at Bologna, at which university he received the degree of doctor in both these sciences, in March 1597, in the 18th year of his age. He still remained at that place, however, attending the public hospitals, under the direction of the most eminent physicians, for some time; and afterwards went to Rome, where he united the study of anatomy and surgery, with that of medicine. Returning to his native country, he commenced the practice of his profession, where he soon acquired so much reputation, that the marquis of Bentivoglio induced him to settle at Ferrara, as professor of surgery in the university of that city. Here, however, he met with considerable opposition and enmity from the established practitioners, who interdicted him from prac-

ting, unless he would submit to their examinations; with which he at length complied, and gave abundant proofs of superior talents and acquirements. He soon attained the highest professional reputation at Ferrara, and gained the greatest applause from numerous classes of students by his able conduct in the chair, until he was seized with a severe illness, under the impression of which he was induced to enter into the fraternity of Capuchins, and afterwards assumed the habit of the order. He still continued, however, to practise medicine and surgery, in his new condition, with a success that acquired him the confidence of persons of the first rank, especially of Francis I. duke of Modena. But the severity of his sufferings from the stone induced him, in 1647, to repair to Bologna, for the purpose of relieving himself by undergoing the operation of lithotomy; but he survived it a very short time, and died at the age of sixty-eight.

Magatus was the author of a considerable improvement in the art of surgery, by his work entitled "De rara Medicatione Vulnerum, seu, de Vulneribus raro tractandis," Venice, 1616, which he also strenuously inculcated in his lectures, and the good effects of which he had often witnessed during his attendance at Rome. This was the rejection of tents in the treatment of wounds, and the recommendation of a simple easy method of dressing, without the irritation of frequently cleansing and rubbing the tender granulations; a practice which he supported at great length by sound and rational arguments, tinged a little, however, by the Galenical theories. His work contains also a number of valuable observations respecting particular wounds; and it has an appendix, relating to gun-shot wounds, in which he refutes the notion of their being envenomed, or attended with cauterization. Sennertus published a criticism on his work, containing a defence of the use of tents; to which Magatus, now a monk, replied, in the name of his brother John Baptist, (if that was not his own conventional name) by publishing a pamphlet, with the title of "Tractatus, quo rara Vulnerum deligatio defenditur contra Sennertum," 1627, which is to be found in the Venice edition of the former work, published in 1676. Eloy Dict. Hist. de la Méd. Gen. Biog.

MAGAZINE, LITERARY, a miscellaneous, periodical pamphlet, containing a variety of essays, in prose and verse. The term, as applied to literature, is modern, but is now become of extensive and popular import. In England it was first employed in "The Gentleman's Magazine," the first number of which was published January 1, 1731; and this has been regularly continued every month from that time to the present. This was not the earliest periodical publication in monthly numbers, as one had appeared in the year 1681, under the title of "The Monthly Recorder of all true Occurrences both Foreign and Domestic." Soon after "The Gentleman's Magazine," a rival work, under the title of "The London Magazine," was published, but this was discontinued in the year 1785.

"The invention of this new species of publication," observes Dr. Kippis, in his memoir of Edward Cave, in the Biographia Britannica, "may be considered as something of an epocha in the literary history of the country. The periodical publications before that time, (*i. e.* 1731) were almost wholly confined to political transactions and to foreign and domestic occurrences: but the magazines have opened a way for every kind of inquiry. The intelligence and discussion contained in them are very extensive and various; and they have been the means of diffusing a general habit of reading through the nation; which in a certain degree hath enlarged the public understanding.

Many young authors, who have risen to considerable eminence in the literary world, have here made their first attempts in composition. If it were not an invidious task, the history of them would be no incurious or unentertaining subject." In a former part of this dictionary, we have given a brief history of Newspapers, Magazines under the term "Journal," but if the reader be desirous of obtaining an ample account of periodical literature, he will find it fully narrated in "Nichols's Literary Anecdotes of the eighteenth Century," 6 vols. 8vo.

MAGAZINE, in the *Military Art*, a place in fortified towns, where all sorts of stores are kept; and where carpenters, wheelwrights, smiths, &c. are employed in making things needful to furnish out the train of artillery.

MAGAZINE, *Powder*, is a building constructed for keeping large quantities of powder. These magazines were formerly towers erected in the town walls; but many inconveniences attending this situation of them, they are now placed in different parts of the town. They were at first constructed with Gothic arches; but M. Vauban, finding these too weak, constructed them in a semicircular form, of the following dimensions, *viz.* sixty feet long within, and twenty-five broad; the foundation eight or nine feet thick; and eight feet high from the foundation to the spring of the arch; the floor about two feet from the ground, to prevent damp; and consequently six feet for the height of the story.

The thinnest part or hanches of the arch is three feet thick, and the arch made of four lesser ones one over the other, and the outside of the whole terminated in a slope to form the roof; from the highest part of the arch to the ridges is eight feet, which makes the angle somewhat greater than ninety degrees; the two wings, or gable ends, are four feet thick, raised somewhat higher than the roof, as is customary in other buildings; as to their foundations they are five feet thick, and as deep as the nature of the ground required.

The piers or long sides are supported by four counterforts, each six feet broad, and four feet long, and their interval twelve feet; between the intervals of the counterforts, are air-holes, in order to keep the magazine dry and free from dampness; the dices of these air-holes are commonly a foot and a half every way, and the vacant space round them three inches, made so, as the in and outsides be in the same direction. The dices serve to prevent an enemy from throwing fire in to burn the magazine, and for a farther precaution, it is necessary to stop these holes with several iron plates, that have small holes in them like a skimmer, otherwise fire might be tied to the tail of some small animal, and so drive it in that way; this would be no hard matter to do, since, where this precaution had been neglected, egg-shells have been found within, that have been carried there by weasels.

To keep the floor from dampness, beams are laid long ways, and to prevent these beams from being soon rotten, large stones are laid under them; these beams are eight or nine inches square, or rather ten high and eight broad, which is better, and eighteen inches distant from each other; their interval is filled with dry sea coals, or chips of dry stones, then over these beams are others laid cross-ways, four inches broad, and five high, which are covered with two-inch planks.

M. Belidor would have brick walls made under the floor, instead of beams, and a double floor laid on the cross-beams; which does not appear to be so well as the manner proposed here; the reader is, however, at liberty to choose the method he likes best.

To give light to the magazine, a window is made in each wing, which is shut up by two shutters of two or three inches thick, one within and the other without it; that which is on the outside is covered with an iron plate, and is fastened with bolts, as well as that on the inside. These windows are made very high, for fear of accidents, and are opened by means of a ladder, to give air to the magazine in fine dry weather.

There is likewise a double door made of strong planks, the one opens on the outside, and the other within; the outside one is also covered with an iron plate, and both are locked by a strong double lock; the store-keeper has the key of the outside, and the governor that of the inside: the door ought to face the south nearly, if possible; in order to render the magazine as light as can be, and that the wind blowing in may be dry and warm. Sometimes a wall of ten feet high is built round the magazine about twelve distant from it, to prevent any thing from approaching it without being seen. Mr. Muller has proposed some alterations by way of improvement, in M. Vauban's construction, for which see his *Practical Fortification*, p. 219, &c.

If large magazines are required, the piers or side-walls which support the arch should be ten feet thick, seventy-two feet long, and twenty-five feet high; the middle wall, which supports the two small arches of the ground floor, eight feet high, and eighteen inches thick, and likewise the arches: the thickness of the great arch should be three feet six inches, and the counterforts, as well as the air-holes, the same as before. Magazines of this kind should not be erected in fortified towns, but in some inland part of the country near the capital, where no enemy is expected. It has been observed, that after the centres of semicircular arches are struck, they settle at the crown and rise up at the hanches; now as this shrinking of the arches must be attended with ill consequences, by breaking the texture of the cement after it has been partly dried, and also by opening the joints of the vousoirs at one end; Dr. Hutton, in his *Treatise on Bridges*, has proposed to remedy this inconvenience, with regard to bridges, by the arch of equilibration; and as the ill effect is much greater in powder magazines, he has also proposed to find an arch of equilibration for them also; and to construct it when the span is twenty feet, the pitch or height ten, which are the same dimensions as those of the semicircle, the inclined exterior walls, at top, forming an angle of 113° , and the height of their angular point above the top of the arch equal to seven feet; this curious question was answered in 1775, by the Rev. Mr. Wildbore, and the solution of it may be found in Hutton's *Miscellanea Mathematica*.

MAGAZINE, *Artillery*, or the magazine to a field battery, is usually made about fifty or sixty yards behind the platform. This is a cavity dug in the ground about four feet deep, and the earth thrown between the pit and the platform; the sides of the pit are sometimes planked round to keep it dry and to prevent the earth from crumbling in; and the powder-barrels placed here are covered with hurdles and earth, or tanned hides, to preserve the powder from wet or fire. The communication to the magazine is by a sloping trench beginning to descend about five or six yards behind the platform; and the earth is thrown on that side where it will most conveniently cover the persons who remove the barrels of powder from the great magazine to the battery or small magazine. When there are many cannons in the battery, and the service is quick, it is customary to have, for every two pieces, a small magazine to hold twenty or thirty barrels of powder; this is placed about fifteen or twenty yards behind the platform, and against the mer-

lon between the cannon; and as these barrels are used, they are replaced by others from the great magazine. At each magazine a sentinel is placed to prevent accidents; and in order to prevent persons from coming into the battery and magazines who have no business there, a trench is sometimes dug behind the magazine and carried into the trenches, which communicate between the magazine and battery.

MAGAZINE, the apartment used to keep the powder in; which in large ships is situated forwards, and in small ships abaft. It should always be situated as low down as possible.

MAGBOTE, or MEGBOTE, formed of the Saxon *mag*, *i. e.* cognatus, and *bote*, *compensatio*, in our *Old Writers*, a compensation for the slaying or murder of one's kinsman, in ancient times, when corporal punishments for murder, &c. were sometimes commuted into pecuniary fines, if the friends and relations of the party were so satisfied.

MAGDALA, in *Ancient Geography*, a town of Palestine, on the western bank of the lake Tiberias.

MAGDALEINE, in *Geography*, the name of an island situated at the bottom of False bay, near the Cape of Good Hope, in which is a great resort of sea wolves, and of penguins, named "Manchots."

MAGDALEN. *Religious of St. Magdalen*, is a denomination given to divers communities of nuns, consisting, generally, of penitent courtezans; sometimes, also, called *Magdalanettes*.

Such are those at Metz, established in 1452; those at Paris, in 1492; those at Naples, first established in 1324; and endowed by queen Sancha, to serve as a retreat for public courtezans, who should betake themselves to repentance; and those of Rouen and Bourdeaux, which had their original among those of Paris in 1618.

In each of these monasteries there are three kinds of persons and congregations; the first consist of those who are admitted to make vows, and these bear the name of St. Magdalen; the congregation of St. Martha is the second, and is composed of those who it is not judged proper to admit to vows; finally, the congregation of St. Lazarus is composed of such as are detained there by force.

The religious of St. Magdalen at Rome were established by pope Leo X. Clement VIII. settled a revenue on them, and farther appointed that the effects of all public prostitutes, dying intestate, should fall to them; and that the testament of the rest should be invalid, unless they bequeathed a portion of their effects, which was to be at least a fifth part, to them.

MAGDALEN *Hospital*. See HOSPITAL.

MAGDALEN *Islands*, in *Geography*, a cluster of islands in the gulf of St. Lawrence, N.E. of the isle of St. John's, and N.W. of that of Cape Breton. They are inhabited by a few fishermen, and are dangerous to ships sailing near them in foggy weather. The largest, which gives name to the cluster, is situated in N. lat. $47^\circ 25'$. W. long. $61^\circ 20'$.

MAGDALEN *River*, a river of Canada, which runs into the river St. Lawrence. N. lat. $49^\circ 12'$. W. long. $65^\circ 5'$.

MAGDALENA, a small island in the South Pacific ocean, being one of the *Marquesas*; situated nearly in S. lat. $10^\circ 29'$. W. long. $138^\circ 50'$. See MARQUESAS.

MAGDALENA, a town of the island of Cuba; 30 miles S. of Havanna.

MAGDALENA *River*. See MADALENA.

MAGDALENA, *Cape of*, a promontory in the centre of Canada, which has an iron mine abounding with ore and yielding excellent metal.

MAGDALEO, a word used by dispensatory writers, to express any thing made up into a cylindrical form. The common rolls of plasters which the apothecaries make up to be ready for spreading upon occasion, are thus called, as also the rolls of sulphur or common brimstone.

MAGDALGAD, in *Ancient Geography*, a town of Palestine, in the tribe of Judah. Joth. c. xv.

MAGDALIE, or **MAGDALIDES**, the same as Magdalenoes, rolls of sulphur, plaster, &c.

MAGDALUM, in *Ancient Geography*, a place of Egypt, on the coast of the Red sea, between Baal-Zephen and Philabiroth.

MAGDEBURG, in *Geography*, a duchy surrounded by the Mark of Brandenburg, the duchy of Brunswick, the principalities of Halberstadt and Anholt, the county of Mansfeld, and the electorate of Saxony. The country belonging to this duchy is, in general, level. Although fuel is scarce, it has several mines of pit-coal, and by means of its rivers, particularly the Elbe, which pervades the duchy, obtains wood from the neighbouring provinces. Its salt springs afford a supply of salt sufficient for the demands of all Germany. In 1703, the whole duchy contained 35 towns and 431 villages. From the years 1750 to 1756, the number of inhabitants, estimated by the burials, amounted to 330,000. According to Hoeck's account in 1801, the number is stated at 275,262. The states of the country consisted of prelates, the nobility, and the cities. The Reformation was introduced into this duchy in the sixteenth century, and about the middle of the succeeding century Lutheranism was the only religion that was tolerated; but since that time French and German Calvinist refugees have been received, and under king Frederick-William, the private exercise of the Roman Catholic worship was tolerated both at Magdeburg and Halle. The bishopric of Magdeburg was formed out of a Benedictine convent, founded by the emperor Otho I. in 937, and converted into an archbishopric in 967. By the peace of Westphalia, in 1648, the house of Brandenburg obtained, under certain stipulations, the reversion of this archbishopric, and in 1680 the actual possession of it. The duchy had its own regency, which, in 1714, was removed from Halle to Magdeburg, and consisted of two senates; but the cathedral chapter was afterwards excluded from any part in the government. The annual revenues amounted to above 800,000 rix-dollars. By the peace of Tilfit in 1807, that part of the duchy, which lies on the left side of the Elbe, was ceded by the king of Prussia to the new kingdom of Westphalia.

MAGDEBURG, a city of Westphalia, the capital of the above-mentioned province, in the circle of Lower Saxony, on the left bank of the Elbe. This was formerly one of the principal trading towns in Germany. It is strongly fortified, and has a citadel on an island in the river Elbe. It is well built, and the cathedral square is ornamented with large and elegant houses. Among the principal edifices may be reckoned the king's palace, formerly the episcopal residence, the armoury, the governor's house, and the guild-hall, to which we may add the Lutheran cathedral, which is a superb structure, in the antique taste. The Lutherans have also three collegiate, and six parochial churches, and a convent. The manufactures, which are numerous, consist of woollen cloths and stuffs, silk stuffs, cottons, linen, stockings, hats, leathern gloves, tobacco, snuff, &c. The situation of the Elbe, and the road connecting High and Low Germany, render it convenient for trade. Magdeburg, as early as the time of Charles the Great, was a place of some note; and it attained a considerable degree of prosperity in later times, and became one of the Hanse towns. In the

year 1807, it was taken by the French. The number of inhabitants, in 1798, is stated by Hassel at 30,611, and in 1802, by Krug, at 32,000; 52 miles E.S.E. of Potzdam. N. lat. 52° 8'. E. long. 11° 50'.

MAGDELA, a town of Germany, in the principality of Weimar; 7 miles S.E. of Weimar.

MAGDELAINÉ, a cluster of small islands in the Mediterranean, near the N. coast of Sardinia. N. lat. 41° 11'. E. long. 9° 36'.

MAGDOLUS, or **MAGDOL**, in *Ancient Geography*, a town situated towards the middle of the frontiers of Lower Egypt, mentioned Jer. c. lxxvi. v. 14. Exod. c. xiv. v. 2. and also by Herodotus l. xi. c. 49. It was not far from the sea. The Itinerary of Antonine places it in the vicinity of the Delta, E. of it, about 12 miles from Pelusium, near the most easterly mouth of the Nile.

MAGEDAN, a town of Judea, situated E. of the lake of Genesareth.

MAGEDO. See **MEGIDDO**. ** Not to be found*

MAGEE, in *Geography*, a town of Hindoostan; 25 miles E. of Bewares

MAGEEYONCOLLA, a town of Burmah; 42 miles N. of Prome.

MAGEGODEVICK, or **EASTERN RIVER**, a river of America, which falls into the bay of Passanaquoddy, and supposed to be the true St. Croix, which forms part of the east boundary line between the United States and New Brunswick.

MAGEGOWN, a town of Hindoostan, in Concan; 25 miles S. of Severndroog.

MAGELHOLM, a small island of Denmark, in the Baltic, near the S. coast of the island of Zealand. N. lat. 54° 43'. E. long. 11° 17'.

MAGELLAN STRAITS, a passage between the Atlantic and Pacific oceans, at the southern extremity of the continent of America; estimated by Bougainville at 342 miles from Cape Virgin Mary, in the Atlantic, S. lat. 52° 24'. W. long. 68° 22', to Cape Pillar, in the Pacific, S. lat. 52° 45'. W. long. 75° 10'. The breadth of it is various in different parts; and it has many capes and bays, affording places of anchorage and security to ships that pass through it. On the north it is bounded by Patagonia, and on the south by Terra del Fuego. These straits were first discovered by Ferdinando Magellan, or Magalhaens, in the service of the crown of Spain, who, in the year 1520, found a passage through them from the Atlantic to the Pacific ocean, (see his biographical article.) Admiral Drake also passed these straits in his voyage round the world; and they have been since passed by several other navigators, viz. commodore Byron in 1764, Wallis in 1766, and Carteret in 1767, Bougainville in 1768, &c. They have been carefully examined by the navigators just mentioned, with regard to their bays, harbours, and headlands; the numerous islands which they contain, and the coasts on both sides, that inclose them; and the tides, currents, and windings that occur in them, through their whole extent. Of the transactions of Byron, Wallis, and Carteret in these straits, we have details in the accounts of their respective voyages, and these, together with the chart, founded on their observations and discoveries, are a very valuable accession to geography. Commodore Byron closes his account of the voyage through these straits, with the following general remarks. "It is probable, that whoever shall read this account, of the difficulties and dangers which attended our passage through the strait of Magellan, will conclude, that it ought never to be attempted again; but that all ships which shall hereafter sail a western course from Europe

Europe into the South seas, ought to go round Cape Horn. I, however, who have been twice round Cape Horn, am of a different opinion. I think that at a proper season of the year, not only a single vessel, but a large squadron might pass the strait in less than three weeks; and I think, to take the proper season, they should be at the eastern entrance some time in the month of December. One great advantage of this passage is, the facility with which fish is almost every where to be procured, with wild celery, scurvy grafs, berries, and many other vegetables in great abundance; for to this I impute the healthiness of my ship's company, not a single man being affected with the scurvy in the slightest degree, nor upon the sick list for any other disorder, notwithstanding the hardship and labour which they endured in the passage, which cost us seven weeks and two days, as we entered the strait on Sunday the 17th of February, and quitted it on Tuesday the 9th of April. Wood and water are also to be procured almost at every anchoring place beyond Fresh-water bay. Our sufferings I impute wholly to our passing the strait just as the sun approached the equinox, when, in this high latitude, the worst weather was to be expected; and indeed the weather we had was dreadful, beyond all description." (Hawksworth's Voyages, vol. i.) Capt. Wallis's account of his passage through this strait terminates with this reflection: "Thus we quitted a dreary and inhospitable region, where we were in almost perpetual danger of shipwreck for near four months, having entered the strait on the 17th of December 1766, and quitted it on the 11th of April 1767; a region where, in the midst of summer, the weather was cold, gloomy, and tempestuous, where the prospects had more the appearance of a chaos than of nature, and where, for the most part, the vallies were without herbage, and the hills without wood." To the account of captain Wallis's voyage is annexed, a table of the courses and distances from point to point, in this strait, as by compass.

MAGELLANIC CLOUDS, in *Astronomy*, whitish appearances like clouds, seen in the heavens towards the south pole, and having the same apparent motion as the stars.

They are three in number, two of them near each other. The largest lies far from the south pole, but the other two are not many degrees more remote from it than the nearest conspicuous star, that is, about eleven degrees. Mr. Boyle conjectures, that if these clouds were seen through a good telescope, they would appear to be multitudes of small stars like the milky way. Boyle's Works abr. vol. i. p. 295.

MAGELLANIC *Goose*, *Anser magellanicus*, in *Ornithology*. See DUCK.

MAGELLANICA TERRA, in *Geography*. See PATAGONIA.

MARGERONG, a town of Hindoostan, in Candehis; 54 miles S. of Indore.

MAGGERI, a town of Hindoostan, in Mysore; 21 miles W. of Bangalore.

MAGGEROE, a large island near the coast of Lapland, separated from it by a strait of the North sea, called "Magger Sund." This island is said to be the most northern land in Europe. N. lat. 71°. E. long. 24° 55'.

MAGGI, JEROME, in *Biography*, a lawyer, philologist, and engineer, was born at Anghiari, in Tuscany, in the earlier part of the sixteenth century; he studied at the principal Italian universities, and while young acquired an intimate acquaintance with antiquities and polite literature. He had scarcely attained to the age of manhood, when he was selected by his townsmen as their ambassador at the court of Florence. In 1558, he was appointed judge at Amatrice, in the kingdom of Naples, but his usual resi-

dence was in the city of Venice, where he wrote the greater part of his learned works. Of his legal studies, the fruit was "A Commentary on the four Books of Justinian's Institutes." In general literature, his principal work was "Variarum Lectionum seu Miscellaneorum," which was elegantly written, and which proves him to have been thoroughly acquainted with the best ancient and modern authors. He appeared as a theologian, in a treatise "De Mundi exustione, et de Die Judicii," commended by Dupin for its learning and elegance. He gave signal proofs of his talents as a poet, but the work by which he acquired the greatest reputation, was relative to the subject of military engineering, entitled "Della Fortificazione delle Citta," which contains a description of many ingenious machines and instruments of his own invention. On account of his skill in this department of science, he was sent to Cyprus, when threatened with invasion by the Turks, and his services as an engineer were of great use in the celebrated siege of that place, and enabled it to hold out a long time, and with vast destruction to the enemy. At length it fell, and Maggi was carried by the Turks as a slave to Constantinople, where he underwent much hardship. In the gloomy solitude of a dungeon, he wrote two pieces, entitled "De Tintinnabulis," and "De Equuleo," the latter, "On the Rack," was probably suggested to him by the reflection on the tortures to which he was daily liable. He was at length, and at the moment when negotiations were carrying on for his deliverance, strangled in his prison, in the year 1572. Bayle.

MAGGI, CHARLES MARIA, an Italian poet of the 17th century, and one of the restorers of good taste in Italy, after the barbarous ravages of the school of Marini. He was born at Milan in 1630, and was secretary to the senate of that city. He died in 1690, and his works were published in the following year by Muratori, at Milan, in four vols 12mo.

MAGGI, in *Geography*, a town of Tunis; 40 miles S.W. of Gabbs.

MAGGIA VAL, an Italian bailiwick, belonging to the Swiss cantons, containing 22 parishes, and 245000 inhabitants of the Catholic religion. It is partly bounded by the duchy of Milan, and the bailiwicks of Livenen and Locarno, and terminated by mountains of eternal snow.—Also, a town of Italy, in the bailiwick of Bellinzona; seven miles W.S.W. from Bellinzona.—Also, a river of Italy, which runs into lake Maggiore, at Locarno.

MAGGIORA, LAGO. See LAKE.

MAGGIORE, an Italian adjective, from *major*, Lat. a word now naturalized in the English language, and synonymous with *greater*, as a *major* 3d implies a greater or sharp 3d, as a *minor* does a less or a flat 3d. These degrees of comparison are of very frequent use in music, the variable intervals amounting to five; as the semitone, the tone, the 3d, the 6th, and the 7th. With regard to the tone and the semitone, their difference of *major* and *minor* can only be expressed in numbers, as we have no notes to express them in our system. The semitone major is the interval of a second minor, as from B to C, or E to F, and its ratio is 15 to 16. The major is the difference between the 4th and 5th, and its ratio 8 to 9. The three other intervals, namely, the 3d, 6th, and 7th, differ constantly from each other by a semitone from the major to the minor. Thus, the 3d minor consists of a tone and a half, and the 3d major of two tones. There are some still smaller intervals, which are called major and minor in theory, as the quarter tone, and the comma; but as these intervals can

only be expressed in numbers, they are imaginary distinctions, and useless in practice.

A mode or key is also said to be major, when the 3d above the key note is major; that is, consisting of four semitones above the base. To modulate from a major key to a minor, and *e contra*, are common musical expressions.

MAGGOT, the common name of the fly-worm, bred in flesh, from the egg of the great blue flesh-fly. Notwithstanding the distaste for this animal, its figure and structure of parts are greatly worth attending to, and may serve as a general history of the class of worms produced from the eggs of flies.

This animal is white and fleshy; its body is composed of a number of rings, like the bodies of caterpillars, and other the like insects, and is capable, at the pleasure of the animal, of assuming different figures, being at times more or less extended in length, and consequently more or less thick.

Notwithstanding that this creature has no legs, it is able to move itself very swiftly, and, in its first attempt to move its body, is extended to its greatest length, and assumes something of the figure of a pointed cone. The pointed part of this cone is the head of the animal, and is not separated from the next ring by any deeper furrow than the rest of the rings are from one another. In some states of the animal one may see two short horns thrust out from the head; but what are more constantly observable, are two brown scaly hooks; these are, however, sometimes hid, and have each of them a sheath, or case, into which the animal can retract them at pleasure. These hooks are bent into an arch, the concavity of which is toward the place on which the creature is placed, and they are thickest at their insertion in the head, and thence diminish gradually, till they terminate in a fine sharp point.

These two hooks are placed in a parallel direction, and can never come together, and therefore cannot serve in the place of teeth to grind the food between, but merely to pull and sever it to pieces, that it may be of a proper size for the mouth of the creature.

The creature has, besides these two hooks, a kind of dart, which is of about a third part of their length, and is placed at an equal distance between them. This also is brown like them, and scaly; it is quite straight, and terminates in a fine point. The hooks have, as it were, two scaly thorns at their points, and this dart seems intended, by reiterated strokes, to divide and break the pieces of flesh these have separated from the rest, into smaller parts.

Immediately below the apertures for the egress of the hooks, is placed the mouth of the animal; the creature does not shew this little opening unless pressed; but if the pressure be properly managed, it will sufficiently open it, and there may be discovered within it a small protuberance, which may very naturally be supposed either the tongue, or the sucker of the animal.

The hooks in this creature not only supply the place of teeth but also of legs; since it is by fastening these hooks into the substance it is placed on, and then drawing up its body to it, that it pulls itself along.

The back of the creature lowers itself by degrees as it approaches the extremity of the belly; and near the place where the back begins to lower itself, are placed the creature's two principal organs of respiration. One may perceive there two small roundish brown spots: these are very easily distinguishable by the naked eye; because the rest of the body of the creature is white: but if we take in the assistance of glasses, each of these spots appears to be a brown circular eminence raised a little above the rest of the body. On each of these spots one may also discover three

oblong oval cavities, something in the shape of button-holes; these are situated in a parallel direction to one another, and their length nearly in a perpendicular direction to that of the body of the animal.

These apertures are so many stigmata or air-holes, openings declined to admit the air necessary to the life of the animal. The creature has six of these stigmata, three in each side of its body.

The great transparency of the body of this insect, gives us an opportunity also to distinguish that it has on each side a large white vessel running the whole length of the body. It is easy to follow the course of these vessels through their whole length, but they are most distinct of all toward their hinder part, and they are always seen to terminate each in the brown spot before described; this leaves us no room to doubt but that they are the two principal tracheæ.

These posterior tracheæ have been well known to the latter naturalists; but there are two others besides these which they seem not to have distinguished. These are situated in the anterior part of the animal, and are easily discovered by following the course of the tracheæ on each side; for though these all the way diminish in their diameters as they approach the head of the animal, yet it may be easily enough seen where they terminate, which is (taking the head for one ring) in the junction of the second and third ring. In this place the naked eye easily discovers a small spot at the extremity of each, which viewed with a good microscope appears to be a plain stigma, of the figure of a funnel with half of it cut off, and very elegantly indented, and as it were fringed at the edges.

These stigmata in the anterior part of the body, are as constant in this creature as the posterior ones, but it seems to have none of those which the caterpillar class are furnished with along their sides; though it seems from the structure of the fly it afterwards transforms itself into, that it ought to have them, since that has stigmata in their places.

The ramifications of the two great tracheæ are very beautifully seen in this creature, especially on his belly; and it is remarkable that no vessel analogous to the great artery in the caterpillar class can be discovered in these; though, if there were any such, their great transparency must needs make them very easily distinguishable; nor could its dilatations and contractions, if so considerable as in that class of animals, be less so. Malpighi imagined that artery, in the caterpillar class, a series of hearts; in its place, however, there may be seen in these animals a true heart. It is easy to observe in these creatures, about the fourth ring of the body, a small fleshy part, which has alternate contractions and dilatations, and is not only discoverable in the body by means of the creature's transparency; but, on making a proper section of them in the second, third, and fourth rings, will be thrown out of the body of the creature, and will afterwards continue its beats for some minutes. Reaumur's Hist. of Insects, vol. iv. p. 166, seq. See LARVA, PUPA, &c. under the article ENTOMOLOGY.

MAGHERA, in *Geography*, a post-town of the county of Londonderry, Ireland; 96 miles N. from Dublin.

MAGHERAFELT a post-town of the county of Londonderry, Ireland, near Lough Neagh; 88 miles N. from Dublin.

MAGHEREE, a cluster of islands on the coast of the county of Kerry, not far from Tralee bay.

MAGI, or **MAGIANS**, a title which the ancient Persians gave to their wise men or philosophers.

The learned are in great perplexity about the original of the word *Magus*, *μαγος*. Plato, Xenophon, Herodotus, Strabo, &c. derived it from the Persian language, in which

it signified a *priest*, or person appointed to officiate in holy things; as *Druid*, among the Gauls; *Gymnosophist*, among the Indians; and *Levite*, among the Hebrews. Others derive it from the Greek *μεγας*, *great*; which they say, being borrowed of the Greeks by the Persians, was returned in the form of *μαγος*; but Vossius, with more probability, brings it from the Hebrew *הגה*, *haga*, to meditate; whence *מגהים*, *maaghim*, in Latin *meditabundi*, q. d. people addicted to meditation. See the sequel of this article.

Magi, among the Persians, answers to *σοφοι*, or *φίλοσοφοι*, among the Greeks; *sapientes*, among the Latins; *Druids*, among the Gauls; *Gymnosophists*, among the Indians; and *prophets*, *priests*, among the Egyptians.

The ancient Magi, according to Aristotle and Laertius, were the sole authors and conservators of the Persian philosophy; and the philosophy principally cultivated among them, was theology and politics; they being always esteemed as the interpreters of all law, both divine and human; on which account they were wonderfully revered by the people. Hence, Cicero observes, that none were admitted to the crown of Persia, but such as were well instructed in the discipline of the Magi; who taught *τα βασιλικά*, and shewed princes how to govern.

Plato, Apuleius, Laertius, and others, agree, that the philosophy of the Magi related principally to the worship of the gods; they were the persons who were to offer prayers, supplications, and sacrifices, as if the gods would be heard by them alone.

They teach their doctrine concerning the nature and origin of the gods, says Laertius, whom they think to be fire, earth, and water; they reject the use of pictures and images, and reprobate the opinion, that the gods are male and female; they discourse to the people concerning justice; they think it impious to consume dead bodies with fire: they allow of marriage between mother and son; they practise divination and prophecy, pretending that the gods appear to them; they forbid the use of ornaments in drefs; they clothe themselves in a white robe; they make use of the ground as their bed, of herbs, cheese, and bread for food, and of a reed for their staff. Strabo also relates, that there were in Cappadocia a great number of Magi, who were called "Pyrethi," or worshippers of fire, and many temples of the Persian gods, in the midst of which were altars attended by priests, who daily renewed the sacred fire, accompanying the ceremony with music.

But according to Lucian, Suidas, &c. this theology or worship of the gods, as it is called, about which the Magi were employed, was little more than the diabolical art of divination; so that *μαγεια*, strictly taken, was the art of divination. These people were held in such veneration among the Persians, that Darius, the son of Hytaspes, among other things, had it engraven on his monument, that he was the master of the Magi.

Philo Judæus describes the Magi to be diligent inquirers into nature, out of the love they bear to truth; and who, setting themselves apart from other things, contemplate the divine virtues the more clearly, and initiate others in the same mysteries.

The Magi, or Magians, formed one of the two grand sects into which the idolatry of the world was divided between 5 and 600 years before Christ. These abominated all those images which were worshipped by the other sect, denominated Sabians, and paid their worship to the Deity under the emblem of fire. Their chief doctrine was, that there were two principles, one of which was the cause of all good, and the other the cause of all evil. The former

was represented by light, and the latter by darkness, as their truest symbols; and of the composition of these two, they supposed, that all things in the world were made. The good god they called Yazdan, denominated by the Greeks Oromasdes; and the evil god Ahraman, whom the Greeks called Arimanius. (See ARIMANIUS.) Concerning these two gods, there was this difference of opinion among them; that whereas some held both of them to have been from all eternity, there were others who contended, that the good god only was eternal, and that the other was created. But they both agreed in this, that there will be a continual opposition between these two, till the end of the world; when the former shall overcome the latter; and that from thenceforth each of them shall have his world to himself; that is, the good god shall have his world with all good men with him; and the evil god his world, with all evil men with him. The good god they always worshipped before fire, as being the cause of light, and especially before the sun, as being, in their opinion, the most perfect fire, and causing the most perfect light; and for this reason they had in all their temples fire continually burning on altars, erected in them for that purpose. Before these sacred fires they performed all their public acts of devotion, as they likewise practised their private devotions before their private fires in their own houses. Such were the tenets of this sect, when Smerdis, who was the principal leader of it, having usurped the crown after the death of Cambyses, was slain by seven princes of Persia; and many of the Magians, who adhered to him, shared likewise the same fate. In consequence of this event, those who adopted the sentiments of this sect, were called, by way of derision, Magians, from *mige-gush*, which signified, in the language of the country then in use, *one that had his ears cropped*. The whole sect of the Magians would soon have sunk into utter extinction, if it had not, in a few years after this period, been revived and reformed by Zoroaster. This celebrated philosopher, called by the Persians Zerdusht, or Zaratush, began about the thirty-sixth year of the reign of Darius to restore and reform the Magian system of religion. He was not only excellently skilled in all the learning of the East that prevailed in his time; but likewise thoroughly versed in the Jewish religion, and in all the sacred writings of the Old Testament that were then extant, whence some have inferred, that he was a native Jew both by birth and profession; and that he had been servant to one of the prophets, probably Ezekiel or Daniel. (See ZOROASTER.) He made his first appearance in Media, in the city of Xiz, now called Aderbijan, as some say; or according to others, in Ecbatana, now called Tauris. Instead of admitting the existence of two first causes, with the Magians, he introduced a principle superior to them both, one supreme God, who created both these, and out of these two produced, according to his sovereign pleasure, every thing else. See Isaiah, v. 5, 6, 7.

In order to avoid making God the author of all evil, he taught that God originally created only light or good, and that darkness or evil followed it by consequence, as the shadow doth the person. According to his doctrine, there was one supreme being independently, and self-existing from all eternity: under him there were two angels, one the angel of light, the author and director of all good; and the other the angel of darkness, who is the author and director of all evil: these two, out of the mixture of light and darkness, made all things that are; and they are in a state of perpetual conflict; so that where the angel of light prevails, there the most is good; and where the angel of darkness

darkness prevails, there the most is evil: this struggle shall continue to the end of the world; and then there shall be a general resurrection, and a day of judgment; after which, the angel of darkness and his disciples shall go into a world of their own, where they shall suffer in everlasting darkness the punishment of their evil deeds; and the angel of light and his disciples shall go into a world of their own, where they shall receive in everlasting light, the reward due unto their good deeds: and henceforward they shall for ever remain separate. See EMANATION.

Plutarch, speaking of the improvement of the religious system of the Magi by Zoroaster, says, (his et Osiris, tom. ii. p. 155.) "some maintain, that, neither is the world governed by blind chance without intelligence, nor is there one mind alone at the head of the universe; but, since good and evil are blended, and nature produces nothing unmixed, we are to conceive, not that there is one store-keeper, who, after the manner of an host, dispenses adulterated liquors to his guests; but that there are in nature two opposite powers, counteracting each other's operations, the one accomplishing good deities, the other evil. To the better power Zoroaster gave the name of Oromasdes, to the worse that of Arimanius; and affirmed, that, of sensible objects, the former most resembled light, the latter darkness. He also taught, that Mithras was a divinity, who acted as moderator between them, whence he was called by the Persians the Mediator." After relating several fabulous tales concerning the contests between the good and evil dæmons, Plutarch, still reciting the doctrines of Zoroaster, proceeds, "The fated time is approaching, in which Arimanius himself shall be utterly destroyed; in which the surface of the earth shall become a perfect plain, and all men shall speak one language, and live happily together in one society." He adds, on the authority of Theopompus, "It is the opinion of the Magi, that each of these gods shall subdue and be subdued by turns for 6000 years, but that, at last, the evil principle shall perish, and men shall live in happiness; neither needing food, nor yielding a shadow; the God who directs these things taking his repose for a time, which, though it may seem long to man, is but short." Diogenes Laertius, after Hecateus, gives it as the doctrine of Zoroaster, that the gods (meaning, doubtless, those of whom he last speaks, Oromasdes and Arimanius) were derived beings.

Those who remain of this sect in Persia and India, in the present day, retain the same doctrines. Zoroaster also caused fire temples to be erected wherever he came: for having feigned that he was taken up into heaven, and there instructed in the doctrines he taught by God himself, out of the midst of a great and most bright flame of fire, he taught his followers, that fire was the truest shechinah of the divine presence; that the sun being the most perfect fire, God had there the throne of his glory, and the residence of his divine presence in a peculiar manner; and next to this in our elementary fire: and, therefore, he ordered them to direct all their worship to God, first towards the sun, which they called Mithra, and next towards their sacred fires: and when they came before these fires to worship, they always approached them on the west side, that having their faces towards them, and also towards the rising sun at the same time, they might direct their worship towards both. And in this posture they always performed every act of their worship. Zoroaster also pretended, that he brought some of the heavenly fire with him on his return, and placed it on the altar of the first fire-temple, which he erected at Xiz, in Media, whence it was propagated to all

the rest. And on this account, their priests carefully watch it, and never suffer it to be extinguished.

Zoroaster, having assumed the character of a divine prophet and reformer of religion, retired into a cave, devoting himself to prayer and meditation, where he composed the book called the *Zend*, in which his pretended revelations were contained. From Media he removed into Bactria; and he went also into India among the Brachmans, and having acquired all their knowledge in mathematics, philosophy, and astronomy, returned and communicated the knowledge he had acquired to his Magians; and thus they became famous for their skill in these sciences; so that a learned man and a Magian were equivalent terms. The vulgar conceived of them as persons actuated and inspired by supernatural powers; and hence those, who pretended to wicked and diabolical acts, assumed the name of Magians; and the term magician acquired its evil meaning. However, this distinguished knowledge was confined to those, who were by way of eminence, the Magi, or the priests; who, like those of the Jews, being of the same tribe, appropriated their learning to their own families. These priests were distributed into three orders, viz. the inferior priests, who conducted the ordinary ceremonies of religion; the superintendants, who governed them, and presided over the sacred fire; and the archimagus, or high-priest, who possessed supreme authority over the whole order; and their churches or temples were also of three sorts, parochial or oratories, in which the people performed their devotions, and where the sacred fire was kept only in lamps; fire-temples, in which fire was kept continually burning on a sacred altar, where the higher order of the Magi directed the public devotions, and the people assembled to perform magical incantations, hear interpretations of dreams, and practise other superstitious; and lastly, the fire-temple in which the archimagus resided, which was visited by the people at certain seasons with peculiar solemnity, and to which it was deemed an indispensable duty for every one to repair, at least once in his life. Zoroaster at length carried his religious system to the royal court of Susa, and made Darius a profelyte, together with most of the great men of the kingdom. Darius was so attached to the Magian system, that he became an archimagus, and ordered, that, among other titles, it should be engraven on his monument, that he was *master of the Magians*. Hence the kings of Persia were considered as pertaining to the sacerdotal tribe, and were always initiated in the sacred order of the Magians, before they took on them the crown, or were inaugurated into the kingdom.

No images or statues were permitted in the Persian worship. Hence, when Xerxes found idols in the Grecian temples, he, by the advice of the Magi, set them on fire, saying, that the gods, to whom all things are open, are not to be confined within the walls of a temple.

Zoroaster, after this success, returned to Balch, in Bactria, where, according to his own institution, he was obliged to reside, as archimagus or head of the sect, and there he reigned in spirituals, with the same authority, over the whole empire, as the king did in temporals; and from hence probably arose the mistake of making him king of Bactria. The principal temple erected at Balch by Zoroaster remained till the 7th century, when his followers being driven by the Mahometans into Carmania, another building of the same kind was raised, to which those who adhered to the ancient Persian religion resorted. Zoroaster, at length, fell a sacrifice to his zeal; for having concerted an enterprize against Argasp, king of

of the oriental Scythians, who was a zealous Sabian, to draw him over to his religion; the Scythian prince invaded Bactria with an army, and slew Zoroaster, with all the priests of this patriarchal church, to the number of eighty persons, and demolished all the fire-temples in that province. This is said to have happened in the 35th year of Darius. Pythagoras derived a great part of his knowledge from Zoroaster, and his disciples the Magians. Pridaux's Conn. vol. i.

Their descendants, the modern Magi, or fire-worshippers, are divided into three classes; of which the first and most learned neither eat nor kill animals; but adhere to the old institution of abstaining from all living creatures. The Magi of the second class refrain only from tame animals; nor do the last kill all indifferently, it being the firm and distinguishing settled notion of them all, *την μεταμολχουσαν ψυχην*, that there is a transmigration of souls. See METEMPSYCHOSIS and GABRES.

The ancient Arabians, like the neighbouring Chaldeans and Persians, seem to have had their wise men, by whom their knowledge, such as they had, was taught, and their religious ceremonies and superstitious arts were practised. Pliny (Hist. Nat. l. xxx. c. 1.) mentions the Arabian Magi, and speaks of Hippocus, an Arabian, as belonging to this order. One of the most ancient sects of the Magi, as the Mosaic history informs us (Exod. iv.), was among the Egyptians. These Magi made use of small images, of various forms, with which they pretended to perform many wonders, and particularly to cure diseases.

MAGIC, MAGIA, *Μαγία*, in its ancient sense, the science, or discipline and doctrine, of the Magi, or wise men of Persia.

The magic which Zoroaster invented was probably nothing more than the performance of certain religious ceremonies, by means of which, good dæmons were supposed to be prevailed upon to communicate supernatural properties and powers to herbs, stones, and other natural bodies, or to afford assistance in other miraculous ways to those who invoked them. In war, it was supposed, that, by the help of magic, the forces of an enemy might be routed, or an army struck with a general panic, as is said to have happened to Ninus, in his war with the Bactrians. In this art the kings of Chaldæa and Persia were instructed, as one of the most useful instruments of government, among a people, whose ignorance and credulity rendered them proper subjects of imposture. For it is justly observed by Plutarch (in Sertorio), that "barbarous nations are naturally prone to superstition; and a weak, illiterate, and fickle multitude, when they are once brought under its dominion, will be more obedient to their priests than to their civil or military leaders." We have given some account of it under the article CHALDEANS.

The Chaldæans, as we are informed by Diodorus Siculus (lib. i.) learned the art of astrology and magic from the Egyptians, who were, from the earliest times, adepts in these fictitious sciences, and by the cultivation of these arts, their priests acquired an irresistible sway over an ignorant and superstitious populace. See the preceding article.

MAGIC, in a more modern sense, is a science which teaches to perform wonderful and surprising effects.

The word magic originally carried with it a very innocent, nay, a very laudable, meaning; being used purely to signify the study of wisdom, and the more sublime parts of knowledge; but in regard the ancient Magi engaged themselves in astrology, divination, sorcery, &c. the term magic, in time, became odious, and was only used to signify an unlawful and diabolical kind of science, depending, as it was pretended, on the assistance of the devil, and departed souls.

If any wonder how so vain and deceitful a science should

gain so much credit and authority over men's minds, Pliny gives the reason of it. It is, says he, because it has possessed itself of three sciences of the most esteem among men, taking from each all that is great and marvellous in it. Nobody doubts but it had its origin in medicine, and that it insinuated itself into the minds of the people, under pretence of affording extraordinary remedies. To these fine promises is added every thing in religion that is pompous and splendid, and that appears calculated to blind and captivate mankind. And, lastly, it mingled judicial astrology with the rest, persuading people, curious of futurity, that it saw every thing to come in the heavens. Agrippa divides magic into three kinds, *natural, celestial, and ceremonial or superstitious.*

MAGIC, *Natural*, is no more than the application of natural active causes to passive things or subjects; by means of which many surprising, but yet natural, effects are produced.

MAGIC, *Celestial*, borders nearly on judiciary astrology; it attributes to spirits a kind of rule, or dominion, over the planets: and to the planets a dominion over men; and on those principles, builds a ridiculous kind of system.

MAGIC, *Superstitious*, or *Geotic*, consists in the invocation of devils, or dæmons: its effects are usually evil and wicked, though very strange, and seemingly surpassing the powers of nature: they are supposed to be produced by virtue of some compact, either tacit or express, with evil spirits; but the truth is, these supposed compacts have not the power that is usually imagined; nor do they produce half those effects ordinarily ascribed to them.

MAGIC *Lantern*, an optic machine contrived by Kircher, (see his *Ars Magna Lucis et Umbræ*, p. 768, 769.), by means of which little coloured images are represented on an opposite wall of a dark room, magnified to any bigness at pleasure, and exhibited in their natural and vivid colours.

MAGIC *Lantern*, *Construction of the*. Suppose ABCD (Plate X. *Optics*, fig. 1.) a common tin lantern, to which is added a tube to draw out, FG. In H is fixed a metallic concave speculum, of a foot diameter at most, or four inches at least: or, in lieu thereof, near the extremity of the tube, there must be placed a convex lens, consisting of a segment of a small sphere, its diameter not exceeding a few inches. The use of this lens is to throw a strong light upon the image; and sometimes a concave speculum is used with the lens, in order to make the image still more vivid. In the focus of the concave speculum, or lens, is placed a lamp L; within the tube where it is soldered to the side of the lantern, is placed a small lens, convex on both sides, being a portion of a small sphere, having its focus about the distance of three inches. The extreme part of the tube, FM, is square, and has an aperture quite through, so as to receive an oblong frame, NO, passed into it; in this frame are round holes, an inch or two in diameter. According to the bigness of these holes are drawn circles, on a plain thin glass; and in these circles are painted any figures or images, at pleasure, with transparent water colours. These images, fitted into the frame, and placed invertedly, at a little distance from the focus of the lens I, will be projected on an opposite white wall of a dark room, prodigiously magnified in all their colours, and in an erect situation. By having the instrument so contrived, as that the lens, I, may move in a slide, the focus may be made, and consequently the image appear distinct, at almost any distance.

Or thus:—Every thing being managed as in the former, into the sliding tube, FG, insert another convex lens K, the segment of a sphere somewhat larger than I. Now, if the picture be brought nearer to I than the distance of the focus, diverging rays will be propagated, as if they proceeded from the object; wherefore, if the lens, K, be so placed,

MAGIC SQUARE.

placed, as that the object is very near its focus, the image will be exhibited on the wall, exceedingly magnified.

MAGIC Lantern, Theory of the. The lamp being placed in the focus of the concave speculum, or any convex glass, the rays will be propagated parallel to each other, and the image will be strongly illumined, and will therefore emit a great number of rays upon the lens I. But, being supposed to be placed near the lens I, the inverted image of the picture inverted must be formed on the opposite wall, exceedingly magnified, after its refraction through the lens; and it will be still the more magnified, as the lens is a segment of a less sphere, and as the picture is placed nearer the focus of the lens; in a dark place, therefore, the picture will be represented prodigiously large and extremely vivid.

To heighten the light, specula are preferred to lenses; the focus of a speculum being nearer than that of a lens. De Chales orders the diameter of the lens, I, to be two, four, or five digits, and in a subduple proportion to the other K; *i. e.* if I be five digits, K must be ten; and the diameter of the speculum, according to the same, is to be two digits. Zahnus chooses to have the diameter of I $\frac{2}{7}$ of a foot; and that of K one foot and a half, &c.

Little animals being included in the magic lantern, in the manner observed in speaking of the microscope, or any little transparent objects fastened to a slice of talc or glass, and substituted instead of images, the magic lantern will become a microscope.

A view of the instrument itself may be seen in *fig. 2*, in which *bhc* is the lens that throws the light of the candle or lamp, *a*, on the object *de*, and *kl* is the lens that magnifies the image, *fg*, on the white wall, *FH*, in a dark room. It is plain, that if the tube, *bnklmc*, be contracted, and the glass, *kl*, be brought nearer the object *de*, the image, *fg*, will be enlarged; and hence, this lantern has been called the *lanterna megalographica*. On the contrary, if the tube be protracted, the image of the object will be diminished. In some magic lanterns, instead of the single lens *kl*, two lenses are used of less curvature, and set at a little distance from each other; and these produce a somewhat better effect than a single lens. Between them is placed a perforated diaphragm.

M. Euler proposed a scheme to introduce vision by reflected light into the magic lantern, as well as the solar microscope, by which many inconveniences to which those instruments are subject, might be avoided. For this purpose, he says, that nothing is necessary but a large concave mirror, perforated as for a telescope, and that the light be so situated, that none of it may pass directly through the perforation, so as to fall on the images of the objects upon the screen. He proposes to have four different machines for objects of different sizes; the first for those of six feet long, the second for those of one foot, the third for those of two inches, and the fourth for those of two lines. An idea of this contrivance is given in *fig. 3*, in which *OD* represents the concave mirror, *E* the object, *l, l*, the lights, and *A* the lens, through which the rays are transmitted to the screen. *Nov. Com. Petrop. vol. iii. p. 363.*

MAGIC Square, a square figure, formed of a series of numbers, in mathematical proportion, so disposed in parallel and equal ranks, as that the sums of each row, taken either perpendicularly, horizontally, or diagonally, are equal.

The several numbers which compose any square number (for instance, 1, 2, 3, 4, 5, &c. to 25 inclusive, which compose the square number 25), being disposed after each other, in a square figure of 25 cells, each in its cell; if then you change the order of these numbers, and dispose them in

the cells in such a manner, as that the five numbers which fill an horizontal rank of cells, being added together, shall make the same sum with the five numbers in any other rank of cells, whether horizontal or vertical, and even the same number with the five in each of the two diagonal ranks: this disposition of numbers is called a *magic square*; in opposition to the former disposition, which is called a *natural square*. See the figure following.

Natural Square.

One would imagine, that these magic squares had that name given them, because this property of all their ranks, which, taken any way, make always the same sum, appeared extremely surprising, especially in certain ignorant ages, when mathematics passed for magic; but there is a great deal of reason to suspect, that these squares merited their name still farther, by the superstitious operations they were employed in, as the construction of talismans, &c. for, according to the childish philosophy of those days, which attributed virtues to numbers, what virtues might not be expected from numbers so wonderful?

However, what was at first the vain practice of makers of talismans and conjurers, has since become the subject of serious research among mathematicians; not that they imagine it will lead them to any thing of solid use or advantage. Magic squares favour too much of their original to be of much use; but only as it is a kind of play, where the difficulty makes the merit, and it may chance to produce some new views of numbers, which mathematicians will not lose the occasion of.

Eman. Moschopolus, a Greek author of no great antiquity, is the first that appears to have spoken of magic squares: and, by the age in which he lived, there is reason to imagine he did not look on them merely as a mathematician. However, he has left us some rules for their construction. In the treatise of Corn. Agrippa, so much accused of magic, we find the squares of seven numbers, *viz.* from three to nine inclusive, disposed magically; and it must not be supposed that those seven numbers were preferred to all the other without some very good reason: in effect, it is because their squares, according to the system of Agrippa and his followers, are planetary. The square of 3, for instance, belongs to Saturn; that of 4, to Jupiter; that of 5, to Mars; that of 6, to the Sun; that of 7, to Venus; that of 8, to Mercury; and that of 9, to the Moon. M. Bachel applied himself to the study of magic squares, on the hint he had taken from the planetary squares of Agrippa, as being unacquainted with the work of Moschopolus, which is only in manuscript in the French king's library; and, without the assistance of any author, he found out a new method for those squares whose root is uneven; for instance, 25, 49, &c. but he could not make any thing of those whose root is even.

After him came M. Frenicle, who took the same subject in hand. A certain great algebraist was of opinion, that whereas the sixteen numbers which compose the square might

MAGIC SQUARE.

be disposed 20922789888000 different ways in a natural square (as from the rules of combination it is certain they may), they could not be disposed in a magic square above sixteen different ways; but M. Frenicle shewed, that they might be thus disposed 878 different ways: whence it appears how much his method exceeds the former, which only yielded the 55th part of magic squares of that of M. Frenicle.

To this inquiry he thought fit to add a difficulty, that had not yet been considered; the magic square of 7, for instance, being constructed, and its 49 cells filled, if the two horizontal ranks of cells, and, at the same time, the two vertical ones, the most remote from the middle, be retrenched, that is, if the whole border or circumference of the square be taken away, there will remain a square, whose root will be 5, and which will only consist of 25 cells. Now, it is not at all surprising, that the square should be no longer magical, because the ranks of the large ones were not intended to make the same sum, excepting when taken entire with all the seven numbers that fill their seven cells; so that being mutilated each of two cells, and having lost two of their numbers, it may be well expected, that their remainders will not any longer make the same sum. But M. Frenicle would not be satisfied unless when the circumference or border of the magic square was taken away, and even any circumference at pleasure, or, in fine, several circumferences at once, the remaining squares were still magical: which last condition, no doubt, made these squares vastly more magical than ever.

Again, he inverted that condition, and required that any circumference taken at pleasure, or even several circumferences, should be inseparable from the square; that is, that it should cease to be magical when they were removed, and yet continue magical after the removal of any of the rest. M. Frenicle, however, gives no general demonstration of his methods, and frequently seems to have no other guide but chance. It is true, his book was not published by himself, nor did it appear till after his death, *viz.* in 1693.

In 1703, M. Poignard, canon of Brussels, published a treatise of sublime magic squares. Before him there had been no magic squares made but for serieses of natural numbers that formed a square; but M. Poignard made two very considerable improvements. 1°. Instead of taking all the numbers that fill a square, for instance, the thirty-six successive numbers, which would fill all the cells of a natural square, whose side is six, he only takes as many successive numbers as there are units in the side of the square, which, in this case, are six; and these six numbers alone he disposes in such manner in the thirty-six cells, that none of them are repeated twice in the same rank, whether it be horizontal, vertical, or diagonal; whence it follows, that all the ranks, taken all the ways possible, must always make the same sum, which M. Poignard calls repeated progression. 2°. Instead of being confined to take these numbers according to the series and succession of the natural numbers, that is, in an arithmetical progression, he takes them likewise in a geometrical progression, and even in an harmonical progression. But with these two last progressions the magic must necessarily be different to what it was: in the squares filled with numbers in geometrical progression, it consists in this, that the products of all the ranks are equal; and, in the harmonical progression, the numbers of all the ranks continually follow that progression: he makes squares of each of these three progressions repeated.

This book of M. Poignard gave occasion to Mr. de la Hire to turn his thoughts the same way, which he did with such success, that he seems to have well-nigh completed the

theory of magic squares. He first considers uneven squares; all his predecessors on the subject having found the construction of even ones by much the most difficult; for which reason M. de la Hire reserves those for the last. This excess of difficulty may arise partly from hence, that the numbers are taken in arithmetical progression. Now in that progression, if the number of terms be uneven, that in the middle has some properties which may be of service; for instance, being multiplied by the number of terms in the progression, the product is equal to the sum of all the terms.

M. de la Hire proposes a general method for uneven squares, which has some similitude with the theory of compound motions, so useful and fertile in mechanics. As that consists in decomposing motions, and resolving them into others more simple; so does M. de la Hire's method consist in resolving the square that is to be constructed into two simple and primitive squares. It must be owned, however, it is not quite so easy to conceive those two simple and primitive squares in the compound or perfect square, as in an oblique motion to imagine a parallel and perpendicular one.

Suppose a square of cells, whose root is uneven, for instance 7; and that its forty-nine cells are to be filled magically with numbers, for instance, the first 7. M. de la Hire, on the one side, takes the first seven numbers, beginning with unity, and ending with the root 7; and on the other 7, and all its multiples to 49, exclusively; and as these only make six numbers, he adds 0, which makes this an arithmetical progression of seven terms, as well as the other; 0, 7, 14, 21, 28, 35, 42. This done, with the first progression repeated, he fills the square of the root 7 magically: in order to this, he writes in the first seven cells of the first horizontal rank, the seven numbers proposed, in what order he pleases, for that is absolutely indifferent; and it is proper to observe here, that those seven numbers may be ranged in 5040 different manners in the same rank. The order in which they are placed in the first horizontal rank, be it what it will, is that which determines their order in all the rest. For the second horizontal rank, he places in its first cell, either the third, the fourth, the fifth, or the sixth number, from the first number of the first rank; and after that writes the six others in order as they follow. For the third horizontal rank, he observes the same method with regard to the second, that he observed in the second with regard to the first, and so of the rest. For instance, suppose the first horizontal rank filled with the seven numbers in their natural order, 1, 2, 3, 4, 5, 6, 7; the second horizontal rank may either commence with 3, with 4, with 5, or with 6; but in this instance it commences with 3; the third rank

1	2	3	4	5	6	7
3	4	5	6	7	1	2
5	6	7	1	2	3	4
7	1	2	3	4	5	6
2	3	4	5	6	7	2
4	5	6	7	1	2	3
6	7	1	2	3	4	5

therefore must commence with 5, the fourth with 7, the fifth with 2, the sixth with 4, and the seventh with 6. The commencement of the ranks which follow the first being thus determined, the other numbers, as we have already observed, must be written down in the order wherein they stand in the first, going on to 5, 6, and 7, and returning to 1, 2, &c. till every

MAGIC SQUARE.

every number in the first rank be found in every rank underneath, according to the order arbitrarily pitched upon at first. By this means it is evident, that no number whatever can be repeated twice in the same rank; and by consequence, that the seven numbers 1, 2, 3, 4, 5, 6, 7, being in each rank, must of necessity make the same sum.

It appears, from this example, that the arrangement of the numbers in the first rank being chosen at pleasure, the other ranks may be continued in four different manners; and since the first rank may have 5040 different arrangements, there are no less than 20,160 different manners of constructing the magic square of seven numbers repeated.

1	2	3	4	5	6	7
2	3	4	5	6	7	1
3	4	5	6	7	1	2
4	5	6	7	1	2	3
5	6	7	1	2	3	4
6	7	1	2	3	4	5
7	1	2	3	4	5	6

1	2	3	4	5	6	7
7	1	2	3	4	5	6
6	7	1	2	3	4	5
5	6	7	1	2	3	4
4	5	6	7	1	2	3
3	4	5	6	7	1	2
2	3	4	5	6	7	1

The order of the numbers in the first rank being determined; if in beginning with the second rank, the second number 2, or the last number 7, should be pitched upon, in one of those cases and repeated; and, in the other case, the other diagonal would be false, unless the number repeated seven times should happen to be 4; for four times seven is equal to the sum of 1, 2, 3, 4, 5, 6, 7: and, in general, in every square consisting of an unequal number of terms, in arithmetical progression, one of the diagonals would be false according to those two constructions, unless the term always repeated in that diagonal were the middle term of the progression. It is not, however, at all necessary to take the terms in an arithmetical progression; for, according to this method, one may construct a magic square of any numbers at pleasure, whether they be according to any certain progression, or not. If they be in an arithmetical progression, it will be proper, out of the general method, to except those two constructions, which produce a continual repetition of the same term, in one of the two diagonals; and only to take in the case, wherein that repetition would prevent the diagonal from being just: which case being absolutely disre-

garded, when we computed, that the square of 7 might have 20,160 different constructions; it is evident, that by taking that case in, it must have vastly more.

To begin the second rank with any other number besides the second and the last, must not, however, be looked on as an universal rule: it holds good for the square of 7; but if the square of 9, for instance, were to be constructed, and the fourth figure of the first horizontal rank were pitched on for the first of the second, the consequence would be, that the fifth and eighth horizontal ranks would likewise commence with the same number, which would therefore be repeated three times in the same vertical rank, and occasion other repetitions in all the rest. The general rule, therefore, must be conceived thus: let the number in the first rank pitched on, for the commencement of the second, have such an exponent of its quota, that is, let the order of its place be such, as that if an unit be taken from it, the remainder will not be any just quota part of the root of the square; that is, cannot divide it equally. If, for example, in the square of 7, the third number of the first horizontal rank be pitched on for the first of the second, such construction will be just; because the exponent of the place of that number, viz. 3, subtracting 1, that is, 2 cannot divide 7. Thus also might the fourth number of the same first rank be chosen, because $4 - 1$, viz. 3, cannot divide 7; and, for the same reason, the fifth or sixth number might be taken: but in the square of 9, the fourth number of the first rank must not be taken, because $4 - 1$, viz. 3, does divide 9. The reason of this rule will appear very evidently, by considering in what manner the returns of the same numbers do or do not happen, taking them always in the same manner in any given series. And hence it follows, that the fewer divisions the root of any square to be constructed has, the more different manners of constructing it there are; and that the prime numbers, i. e. those which have no divisions, as 5, 7, 11, 13, &c. are those whose squares will admit of the most variations in proportion to their quantities.

The squares constructed, according to this method, have some particular properties not required in the problem; for the numbers that compose any rank parallel to one of the two diagonals, are ranged in the same order with the numbers that compose the diagonal to which they are parallel. And as any rank parallel to a diagonal must necessarily be shorter, and have fewer cells, than the diagonal itself, by adding to it the correspondent parallel, which has the number of cells by which the other falls short of the diagonal, the numbers of those two parallels, placed, as it were, end to

First Primitive.

1	2	3	4	5	6	7
3	4	5	6	7	1	2
5	6	7	1	2	3	4
7	1	2	3	4	5	6
2	3	4	5	6	7	1
4	5	6	7	1	2	3
6	7	1	2	3	4	5

end, still follow the same order with those of the diagonal: besides, that their sums are likewise equal; so that they are magical on another account. Instead of the squares, which we have hitherto formed by horizontal ranks, one might also form them by vertical ones; the case is the same in both.

All we have hitherto said regards only the first primitive square, whose numbers, in the proposed example, were 1, 2, 3, 4, 5, 6, 7; here still remains the second primitive, whose numbers are

MAGIC SQUARE.

Second Primitive.

0	7	14	21	28	35	42
21	28	35	42	0	7	14

7	14	21	28	35	42	0
28	35	42	0	7	14	21

are 0, 7, 14, 21, 28, 35, 42. M. de la Hire proceeds in the same manner here as in the former; and this may likewise be constructed in 20,160 different manners, as containing the same number of terms with the first. Its construction being made, and of consequence all its ranks making the same sum, it is evident, that if we bring the two into one, by adding together the numbers of

come vastly short of expressing all the possible constructions of a perfect magic square of the 49 first numbers.

As to the *even* squares, he constructs them like the *uneven* ones, by two primitive squares; but the construction of *primitives* is different in general, and may be for a great number of ways; and those general differences admit of a great number of particular variations, which give as many different constructions of the same even square. It scarcely seems possible to determine exactly, either how many general differences there may be between the construction of the primitive squares of an even square, and an uneven one; nor how many particular variations each general difference may admit of; and, of consequence, we are still far from being able to determine the number of different constructions of all those that may be made by the primitive squares.

See the Memoirs of the Royal Academy of Sciences, for 1705 and 1710, where this subject is almost exhausted by M. de la Hire and M. Sauveur. See also Saunderfon's Algebra, vol. i. p. 354, &c.

The ingenious Dr. Franklin seems to have carried this curious speculation farther than any of his predecessors in the same way. He has constructed not only a magic square of squares, but likewise a magic circle of squares, of which we shall give some account for the amusement of our readers. The magic square of squares is formed by dividing the great square, as *Plate XI. Analysis, fig. 6.* The great square is divided into 256 small squares, in which all the numbers from 1 to 256 are placed in 16 columns, which may be taken either horizontally or vertically. The properties are as follow:

1. The sum of the sixteen numbers in each column, vertical and horizontal, is 2056.

2. Every half column, vertical and horizontal, makes 1028, or half of 2056.

3. Half a diagonal ascending, added to half a diagonal descending, makes 2056; taking these half diagonals from the ends of any side of the square to the middle thereof; and so reckoning them either upward, or downward; or sidewise from left to right hand, or from right to left.

4. The same with all the parallels to the half diagonals, as many as can be drawn in the great square: for any two of them being directed upward and downward, from the place where they begin to that where they end, their sums will make 2056. The same downward and upward in like manner: or all the same if taken sideways to the middle, and back to the same side again. N. B. One set of these half diagonals and their parallels are drawn in the same square upward and downward. Another such set may be drawn from any of the other three sides.

5. The four corner numbers in the great square added to the four central numbers therein, make 1028; equal to the half sum of any vertical or horizontal column, which contains 16 numbers; and equal to half a diagonal or its parallel.

6. If a square hole (equal in breadth to four of the little squares) be cut in a paper, through which any of the sixteen little squares in the great square may be seen, and the paper be laid on the great square; the sum of all the sixteen numbers, seen through the hole, is equal to the sum of the sixteen numbers in any horizontal or vertical column, *viz.* to 2056.

The magic circle of circles (*fig. 7.*), is composed of a series of numbers, from 12 to 75 inclusive, divided into eight concentric circular spaces, and ranged in eight radii of numbers, with the number 12 in the centre; which number,

the two corresponding cells of the two squares, that is, the two numbers of the first of each, the two numbers of the second, of the third, &c. and dispose them in the forty-nine corresponding cells of a third square; it will likewise be magical, in regard to its rank, formed by the addition of equal sums to equal sums, which must of necessity be equal among themselves. All that remains in doubt is, whether or not, by the addition of the corresponding cells of the two first squares, all the cells of the third will be filled in such manner, as that each not only contains one of the numbers of the progression from 1 to 49, but also that this number be different from any of the rest, which is the end and design of the whole operation.

As to this it must be observed, that if in the construction of the second primitive square, care has been taken in the commencement of the second horizontal rank, to observe an order with regard to the first, different from what was observed in the construction of the first square; for instance, if

Perfect Square.

1	9	17	25	33	41	49
24	32	40	48	7	8	16
47	6	14	15	23	31	39
21	22	31	38	46	5	13
37	47	4	12	20	28	29
11	19	27	35	36	46	3
34	42	43	2	10	18	26

the second rank of the first square began with the third term of the first rank, and the second rank of the second square commence with the fourth of the first rank, as in the example it actually does; each number of the first square may be combined once, and only once, by addition with all the numbers of the second. And as the numbers of the first are here 1, 2, 3, 4, 5, 6, 7,

and those of the second 0, 7, 14, 21, 28, 35, 42, by combining them in this manner, we have all the numbers in the progression from 1 to 49, without having any of them repeated; which is the *perfect* magic square proposed.

The necessity of constructing the two *primitive* squares in a different manner, does not at all hinder but that each of the 20,160 constructions of the one may be combined with all the 20,160 constructions of the other: of consequence, therefore, 20,160 multiplied by itself, which makes 406425600, is the number of different constructions that may be made of the perfect square, which here consists of the 49 numbers of the natural progression. But as we have already observed, that a primitive square of seven numbers repeated may have above 20,160 several constructions, the number 406425600 must

MAGIC SQUARE.

like the centre, is common to all these circular spaces, and to all the radii.

The numbers are so placed, that the sum of all those in either of the concentric circular spaces above mentioned, together with the central number 12, make 360; equal to the number of degrees in a circle.

The numbers in each radius also, together with the central number 12, make just 360.

The numbers in half of any of the above circular spaces, taken either above or below the double or horizontal line, with half the central number 12, make 180: equal to the number of degrees in a semicircle.

If any four adjoining numbers be taken, as if in a square, in the radial divisions of these circular spaces; the sum of these, with half the central number, make 180.

There are, moreover, included four sets of other circular spaces, bounded by circles which are excentric with respect to the common centre; each of these sets containing five spaces. The centres of the circles which bound them are at A, B, C, and D. The set, whose centre is at A, is bounded by dotted lines; the set whose centre is at C is bounded by lines of short unconnected strokes, and the set round D is bounded by lines of unconnected longer strokes, to distinguish them from one another. In drawing this figure by hand, the set of concentric circles should be drawn with black ink; and the four different sets of excentric circles with four kinds of ink of different colours; as blue, red, yellow, and green, for distinguishing them readily from one another.

These sets of excentric circular spaces intersect those of the concentric, and each other; and yet, the numbers contained in each of the excentric spaces, taken all around through any of the 20, which are excentric, make the same sum as those of the concentric; namely, 360, when the central number 12 is added. Their halves also, taken above or below the double or horizontal line, with half the central number, make 180.

Observe, that there is not one of the numbers but what belongs at least to two of the circular spaces; some to three, some to four, some to five: and yet they are all so placed as never to break the required number 360, in any of the twenty-eight circular spaces within the primitive circle.

To bring these matters in view, all the numbers as above-mentioned are taken out, and placed in separate columns, as they stand around both the concentric and excentric circular spaces, always beginning with the outermost and ending with the innermost of each set; and also the numbers as they stand in the eight radii, from the circumference to the centre; the common central number 12 being placed the lowest in each column.

1. In the eight concentric circular space.

14	72	23	65	21	67	12	74

If now we take any four numbers as in a square form, either from No. 1. No. 2. (as suppose from No. 1.) as in the margin; and add half the central number

14 72
25 63
6
number

number 12 to them, the sum will be 180; equal to half the numbers in any circular space, taken above or below the double horizontal line: and equal to the number of degrees in a semicircle. Thus, 14, 72, 25, 63, and 6, make 180. See Franklin's *Exp. and Obs.* p. 350, &c. edit. 4to. 1769; or Ferguson's *Tables and Tracts*, 1771, p. 318, &c.

MAGICAL Picture, in *Electricity*, was first contrived by Mr. Kinnersley, and is thus made: having a large mezzotinto with a frame and glass, *e. gr.* of the king, take out the print, and cut a pannel out of it, near two inches distant from the frame all round; with thin paste or gum-water, fix the border that is cut off on the inside of the glass, pressing it smooth and close; then fill up the vacancy by gilding the glass well with leaf-gold, or brass. Gild likewise the inner edge of the back of the frame all round, except the top part, and form a communication between that gilding and the gilding behind the glass; then put in the board, and that side is finished. Turn up the glass, and gild the fore-side exactly over the back gilding, and when it is dry, cover it, by pasting on the pannel of the picture that hath been cut out, observing to bring the correspondent parts of the border and picture together, by which means the picture will appear of a piece, as at first, only part behind the glass and part before. Hold the picture horizontally by the top, and place a little moveable gilt crown on the king's head. If now the picture be moderately electrified, and another person takes hold of the frame with one hand, so that his fingers touch its inside gilding, and with the other hand endeavour to take off the crown, he will receive a terrible blow, and fail in the attempt. If the picture were highly charged, the consequence might be as fatal as that of high treason. The operator, who holds the picture by the upper end, where the inside of the frame is not gilt, to prevent its falling, feels nothing of the shock, and may touch the face of the picture without danger. If a ring of persons take the shock among them, the experiment is called the conspirators. Franklin's *Exp. and Obs.* p. 30.

MAGICIAN, one who practises the art of magic. See **DIVINATION**, **MAGIC**, and **SORCERY**.

The ancient magicians pretended to extraordinary powers of interpreting dreams, foretelling future events, and accomplishing many wonderful things, by their superior knowledge of the secret powers of nature, of the virtues of plants and minerals, and of the motions and influences of the stars. And as the art of magic among the Pagan nations was founded in their system of theology, and the Magi who first exercised it were the priests of the gods, they pretended to derive these extraordinary powers from the assistance of the gods; which assistance they sought by a great variety of rites and sacrifices, adapted to their respective natures, by the use of charms and superstitious words, and also by ceremonies and supplications: they pretended likewise, in the proper use of their art, to a power of compelling the gods to execute their desires, and commands. An excellent writer has shewn, that the scripture brands all these powers as a shameless imposture, and reproaches those who assumed them with an utter inability of discovering or accomplishing any thing supernatural. (See Isaiah, xlvii. 11, 12, 13. chap. viii. 18, 19. chap. xli. 23, 24. chap. xlv. 25. Jerem. x. 2, 3. 8. 14. chap. xiv. 14. chap. xxvii. 9, 10. chap. l. 36. Pl. xxi. 6. Jonah, ii. 8.) Nevertheless, many of the Christian fathers, as well as some of the heathen philosophers, ascribed the efficacy of magic to evil dæmons: and it was a very prevailing opinion in the primitive church, that magicians and necromancers, both among the Gentiles and heretical Christians, had each their parti-

cular dæmons perpetually attending on their persons, and obsequious to their commands, by whose help they could call up the souls of the dead, foretel future events, and perform miracles. In support of this opinion, it has been alleged, that the names by which the several sorts of diviners are described in scripture, imply a communication with spiritual beings; that the laws of Moses (Exod. xxii. 18. Lev. xix. 26. 31. chap. xx. 27. Deut. xviii. 10, 11.) against divination and witchcraft, prove the efficacy of these arts, though in reality they prove nothing more than their execrable wickedness and impiety; and that pretensions to divination could not have supported their credit in all the heathen nations and through all ages, if some instances of true divination had not occurred. But the strongest argument is derived from the scripture history of the Egyptian magicians who opposed Moses. With regard to the works performed by these magicians, some have supposed that God himself empowered them to perform true miracles, and gave them an unexpected success; but the history expressly ascribes the effects they produced, not to God, but to their own enchantments. Others imagine, that the devil assisted the magicians not in performing true miracles, but in deceiving the senses of the spectators, or in presenting before them delusive appearances of true miracles: against which opinion it has been urged, that it tends to disparage the credit of the works of Moses. The most common opinion since the time of St. Austin, has been, that they were not only performed by the power of the devil, but were genuine miracles, and real imitations of those of Moses. In a late elaborate inquiry into the true sense and design of this part of scripture history, it has been shewn, that the names given to the magicians seem to express their profession, their affectation of superior knowledge, and their pretences both to explain and effect signs and wonders, by observing the rules of their art; and therefore, that they are the persons, whose ability of discovering or effecting any thing supernatural the scripture expressly denies. The learned author farther investigates the design, for which Pharaoh employed them on this occasion: which, he apprehends, was to learn from them, whether the sign given by Moses was truly supernatural, or only such as their art was able to accomplish. Accordingly it is observed, that they did not undertake to outdo Moses, or to controul him, by superior or opposite arts of power, but merely to imitate him, or to do the same works with his, with a view of invalidating the argument which he drew from his miracles, in support of the sole divinity of Jehovah, and of his own mission. The question on this occasion was not, are the gods of Egypt superior to the God of Israel, or can any evil spirits perform greater miracles than those which Moses performed by the assistance of Jehovah? but the question was, are the works of Moses proper proofs, that the God of Israel is Jehovah, the only sovereign of nature, and consequently that Moses acts by his commission; or, are they merely the wonders of nature, and the effects of magic? In this light Philo, (*de Vita Mosis*, lib. i. p. 616.) and Josephus, (*Antiq. Jud.* lib. ii. cap. 13.) place the subject. Moreover, it appears from the principles and conduct of Moses, that he could not allow the magicians to have performed real miracles: because the scripture represents the whole body of magicians as impostors; the sacred writers, Moses in particular, describe all the heathen deities, in the belief of whose existence and influence the magic art was founded, as unsupported by any invisible spirits, and utterly impotent and senseless: the religion of Moses was built on the unity and sole dominion of God, and the sole divinity of Jehovah was the point which Moses was now about to establish, in direct opposition to the

the principles of idolatry; so that if he had allowed that the heathen idols, or any evil spirits supporting their cause, enabled the magicians to turn rods into serpents, and water into blood, and to create frogs, he would have contradicted the great design of his mission, and overthrown the whole fabric of his religion; besides, Moses appropriates all miracles to God, and urges his own, both in general and separately, as an absolute and authentic proof, both of the sole divinity of Jehovah, and of his own mission; which he could not justly have done, if his opposers performed miracles, and even the same with his. On the other hand, it has been urged, that Moses describes the works of the magicians in the very same language as he does his own, (Exod. vii. 11, 12. chap. v. 22. chap. viii. 7.) and hence it is concluded, that they were equally miraculous. To this objection it is replied, that it is common to speak of professed jugglers, as doing what they pretend and appear to do; but that Moses does not affirm, that there was a perfect conformity between his works and those of the magicians, but they did *so*, or in like manner, using a word which expresses merely a general similitude; and he expressly refers all they did, or attempted in imitation of himself, not to the invocation or power of dæmons, or of any superior beings, but to human artifice and imposture. The original words, translated *inchantments*, (Exod. vii. 11, 22. and chap. viii. 7, 18.) import deception and concealment, and ought to have been rendered, *secret sleights* or *jugglings*. Our learned writer farther shews, that the works performed by the magicians did not exceed the cause, or human artifice, to which they are ascribed. Farmer's Diff. on Miracles, 1771, chap. 3. § 3. chap. 4. § 1.

MAGIEROW, in *Geography*, a town of Poland, in the palatinate of Belz; 22 miles S.S.W. of Belz.

MAGILLICUDDY'S REEKS, high mountains in the county of Kerry, Ireland, lying near Killarney. They are supposed to be higher than Mangerton, which is 2500 feet above the level of the sea.

MAGILLIGAN POINT, a cape of Ireland, in the county of Londonderry, at the entrance of Lough Foyle. N. lat. 55° 12'. W. long. 6° 50'.

MAGINI, JOHN ANTHONY, in *Biography*, an Italian mathematician and astronomer, was born at Padua in the year 1556. He acquired an early reputation for acquaintance with the sciences, and was appointed professor of mathematics in the university of Bologna. He was decidedly in favour of the Copernican system, but had not courage openly to avow his opinions; and to prevent any disputes that might occur, and to avoid the penalties of heresy, he taught the doctrine of Ptolemy. He was a practical philosopher, and made the instruments which he used with his own hands; among these were large concave mirrors, full five feet in diameter. He died in 1617, in the sixty-second year of his age, leaving behind him many works that reflect much credit on his memory: among these the most important were his "Ephemerides," in three volumes, from 1580 to 1630: "Theoria Planetarum juxta Copernicæ Observaciones:" "Problemata Astronomica, Gnomonica, et Geographica:" "Italiae Descriptio Chorographica," illustrated with sixty maps. Bayle.

MAGISI, in *Geography*, a town of Brazil, in the government of St. Paul; 36 miles N.E. of St. Paul.

MAGISTER, MASTER, a title frequently found in old writings; noting the person who bore it to have attained some degree of eminence in *scientia aliqua, præsertim in literaria*.

In old times, those we now call *doctors*, were called *magistri*, or *masters*.

MAGISTRY, in *Chemistry*, a term formerly used to

signify a *precipitate*. Since the new nomenclature of chemistry has been introduced, it has become obsolete.

MAGISTRY of *Bismuth*. See BISMUTH.

MAGISTRY of *Lead*. See LEAD.

MAGISTRY of *Sulphur*. See SULPHUR.

MAGISTRATE is the name of any public officer, or ruler, to whom the executive power of the law is committed, either wholly or in part. Of magistrates some are supreme, in whom the sovereign power of the state resides; others are subordinate, deriving all their authority from the supreme magistrates, accountable to him for their conduct, and acting in an inferior secondary sphere. In all tyrannical governments, the supreme magistracy, or the right both of *making* and of *enforcing* the laws, is vested in one and the same man, or one and the same body of men; and whenever these two powers are united together, there can be no public liberty. The magistrate may enact tyrannical laws, and execute them in a tyrannical manner, since he is possessed, in quality of dispenser of justice, with all the power which he, as legislator, thinks proper to give himself. But when the legislative and executive authority are in distinct hands, the former will take care not to entrust the latter with so large a power as may tend to the subversion of its own independence, and therewith of the liberty of the subject. With us in England, therefore, the supreme power is divided into two branches; the one legislative, *viz.* the parliament, consisting of king, lords, and commons; the other executive, consisting of the king alone. See KING, PARLIAMENT, SHERIFF, JUSTICE, &c.

MAGIUS, AL, in *Geography*, a town of Persia, in the province of Farfistan; 45 miles S.W. of Yezd.

MAGLASAN, a town of Persia, in the province of Adirbeizan; 66 miles W. of Tauris.

MAGLEBIE, a town of Denmark, in the island of Zealand; four miles S. of Copenhagen.

MAGLIA, a town of the island of Candia; 16 miles E.S.E. of Candia.

MAGLIABECCHI, ANTHONY, in *Biography*, a person remarkable for his knowledge of books, was born at Florence in 1633. Having attained the elements of the Latin language, he was apprenticed to the business of a goldsmith and jeweller, but his passion for reading induced him to employ every leisure moment in improving his mind, and in laying in large stores of useful knowledge; and at the death of his parents in 1673, he entirely abandoned trade, and devoted himself wholly to the pursuits of literature. By means of an astonishing memory, and almost incessant application, he became more conversant with literary history than any man of his time, and was appointed librarian to the grand duke of Tuscany. He kept up a correspondence with the most learned men in Europe, from many of whom, even in the very highest ranks of life, he received tokens of respect and esteem. Lewis XIV. always commissioned the French literati who visited Italy to salute Magliabecchi in his name. To those who visited him through motives of mere curiosity, he was distant and reserved; but to the truly learned, no man was more communicative of his knowledge, and many of the most eminent scholars of the time have expressed their obligations to him. He could most readily direct an author to all the works which treated upon the subject on which he was writing. So expert and accurate was he in this respect, that he has been called a living library. He was taken seriously ill in 1708, and upon his recovery Ferdinand wished him to lodge in the palace, and prepared for him a commodious apartment, and a large room for his books. Here he resided a few months, and then returned to his own cottage, where he died, at the age

age of eighty-one, in the year 1714. Magliabecchi was a man of a most forbidding and savage aspect, and exceedingly negligent of his person. His habits were solitary and cynical, never indulging in the pleasures of society, or the gratifications of sense. He refused to be waited upon, and rarely took off his clothes to go to bed. In the midst of the coldest winter he made the same cloak a covering for the day and the night. His dinner was commonly three hard boiled eggs, with a draught of water. He spent some hours in each day at the palace library, but is said never in his life to have gone farther from Florence than to Pratz, whither he once accompanied cardinal Norris to see a manuscript. He had a small window in his door, through which he could see all those who approached him, and if he did not wish their company he would not admit them.

MAGLIANO, in *Geography*, a town of Italy, in the Sabina, a bishop's see; 28 miles N. of Rome. N. lat. 42° 20'. E. long. 12° 28'.—Also, a town of Etruria; 12 miles N.E. of Orbitello.

MAGLOI, a town of Bosnia, on the Bosna; 21 miles N. of Serajo.

MAGMA, *Μαγμα*, among *Chemists*, &c. the dregs or remainings of a composition remaining after all the more fluid parts are expressed.

It is a word used by medical writers on many occasions, sometimes in a very lax, and sometimes in a more appropriated sense. Some writers use it to express a mass of any thing; others for a thick ointment made up with very little fluid matter to prevent its running; and others for the remains of an ointment after expression from its ingredients. Galen restrains the word *magma* to express only the faces of myrobalsans.

MAGNA ARTERIA, in *Anatomy*. See AORTA and ARTERY.

MAGNA *Affixæ Eligenda*, a writ directed to the sheriff to summon four lawful knights before the justice of assize, there, upon their oaths, to choose twelve knights of the vicinage, &c. to pass upon the *great assize* between A. B. plaintiff, and C. D. defendant, &c. See ASSISES.

MAGNA *Charta*, the *great charter* of liberties of England, signed and sealed by king John in a conference between the king and barons at Runnemeade, between Windsor and Staines, June 19th, A. D. 1215, and confirmed by Hen. III. and Edward I.

The reason of its being termed *Magna*, or *great*, is either because of the excellency of the laws and liberties therein contained, or because there was another charter, called *Charta de Foresta*, established with it, which was the lesser of the two; or else because it contained more than any other charters; or in regard of the wars and troubles in the obtaining of it; or of a great and remarkable solemnity in the denouncing excommunications against the infringers of it.

Magna Charta may be said to derive its origin from king Edward the Confessor, who granted divers liberties and privileges, both civil and ecclesiastical, by charter: the same, with some others, were also granted and confirmed by king Henry I., soon after his coronation and agreeably to an oath by which he had bound himself before he was crowned, by a celebrated great charter.

By this charter he restored the Saxon laws which were in use under Edward the Confessor, but with such alterations, or (as he styled them) "emendations, as had been made in them by his father, with the advice of his parliament," at the same time annulling "all evil customs and illegal exactions, by which the realm had been unjustly oppressed." Some of these grievances were specified in the charter, and the redress of them was there expressly enacted. It

VOL. XXII.

also contained very considerable mitigations of those feudal rights claimed by the king over his tenants, and by them over theirs, which either were the most burthenfome in their own nature, or had been made so by an abusive extension. In short, all the liberty, that could well be consistent with the safety and interest of the lord in his fief, was allowed to the vassal by this charter, and the profits due to the former were settled according to a determined and moderate rule of law. According to the words of one of our greatest antiquaries, sir Henry Spelman, "it was the original of king John's Magna Charta, containing most of the articles of it, either particularly expressed, or in general, under the confirmation it gives to the laws of Edward the Confessor." So mistaken are they, says lord Lyttelton, who have supposed that all the privileges granted in Magna Charta were "innovations" extorted by the arms of rebels from king John!—a notion which seems to have been first taken up, not so much out of ignorance, as from a base motive of adulation to some of our princes in later times, who, endeavouring to grasp at absolute power, were desirous of any pretence to consider those laws, which stood in their way, as violent encroachments made by the barons on the ancient right of the crown; whereas they were in reality restitutions and sanctions of ancient rights, enjoyed by the nobility and people of England in former reigns; or limitations of powers which the king had illegally and arbitrarily stretched beyond their due bounds. In some respects, says our author, this charter of Henry I. was more advantageous to liberty than *Magna Charta* itself. (See HENRY I.) In confirmation of sir Henry Spelman's opinion above-mentioned, we may allege the testimony of an ancient historian. Matthew Paris tells us, that, in the year 1215, the barons came in arms to king John at London, and demanded of him that certain liberties and laws of king Edward, with other liberties granted to them, and to the kingdom and church of England, should be confirmed, "as they were contained and set down in the charter of king Henry I. and in the laws above-mentioned." And the same historian, where he mentions the "capitula," or rough draught of the great charter, delivered to John by the barons, says, that the articles thereof "were partly written before, in the charter of king Henry I. and partly taken out of the ancient laws of king Edward." These passages, and also what he says before, of the barons having sworn at St. Edmund's Bury, to make war on the king, till he should confirm to them, by a charter under his seal, the laws and liberties granted in the charter of Henry I., sufficiently shew, that they understood and intended this charter to be the original and foundation of that which they demanded and obtained from John. With regard to another passage that occurs in Matthew Paris, relating to the charter of Henry I. and connected with his account of a convention or synod held in London under Stephen Langton, archbishop of Canterbury, in the year 1213, it imports that the charter of king Henry was then a "novelty" to the barons, and that they expressed a surprise of joy at hearing a copy of it read, which the archbishop told them was "just found." But from the same historian we learn that, after the charter was given, the king ordered as many transcripts of it to be made as there were counties in England, and to be laid up, as records, in the abbeys of every county. Besides, the first charter of Stephen "confirms the liberties and good laws, which his uncle king Henry gave and granted, and all good laws and good customs, which the nation had enjoyed in the time of Edward the Confessor," words which evidently refer to the charter. It was also confirmed more expressly by king Henry II. "How is it possible then," says lord

M

Lyttelton,

Lyttelton, "that in the reign of his son it should be so difficult to produce a single transcript of it, and that even the remembrance of what it contained should be so totally lost among the principal nobles? The strong objections to so strange a story did not escape the penetration of the learned and judicious Dr. Blackstone. In his accurate edition of the charters, he takes notice of the great improbability of it; and further observes, that it is mentioned by no other contemporary historian; but that, on the contrary, all of them assign quite different reasons for the confederacy of the barons." Our noble author adds, "that the credit of this story is still more weakened, by its being only delivered upon common fame (*ut fama refert*), though it is said to have passed in secret."—"How can one suppose that the particular words of a speech made in secret, could be accurately reported by common fame?"—"That the archbishop should produce to the barons a transcript of the charter, as a proper foundation for their confederacy, and for the demands, or claim of rights, they were to make to the king, I think (says lord Lyttelton) is very probable. But that there could be any difficulty in finding such a transcript, or that it should be regarded by them as a novelty, appears to me quite incredible." "How far Matthew Paris, or rather Roger de Wendover, (from whom the former has transcribed this part of his history), is from being exact in his account of these affairs, we need no better evidence, than the copy he gives us of the charter of king John, which is essentially different from the originals in the British Museum and at Salisbury, and from the entry in the Red Book of the Exchequer. No hypothesis, therefore, can reasonably be built on this passage in that writer; though some have been induced to infer from it, that the charter of Henry I. became obsolete almost as soon as it was given, and was so totally neglected, as to be in a manner forgotten." But to return from this digression, the successors of Henry I. king Stephen, king Henry II. and king John, confirmed, or re-enacted the same; but the last prince violating his charter, the barons took up arms, and his reign ended in blood. Henry III. who succeeded him, after having procured an inquisition to be made by twelve men in each county, what the liberties of England were in the time of Henry I., confirmed, with some alterations, the charter, obtained sword in hand from king John, in 1215, being the present Magna Charta; which he several times confirmed and as often broke again; till in the thirty-seventh year of his reign, he came to Westminster-hall, where, in the presence of the nobility and bishops, with lighted candles in their hands, Magna Charta was read, the king all the while laying his hand on his breast, and at last solemnly swearing faithfully and inviolably to observe all the things therein contained, as he was a man, a Christian, a soldier, and a king. Then the bishops extinguished their candles, throwing them on the ground, crying, "Thus let him be extinguished and sink in hell who violates this charter."

Nevertheless, king Henry in the next year invaded the rights of his people, till the barons levied war against him; and, after various success, he confirmed this charter and the charter of the forests, in the parliament of Marlbridge, and in the fifty-second year of his reign. Afterwards, by statute 25 Edw. I. called *Confirmatio chartarum*, whereby the great charter is directed to be allowed as the common law, all judgments contrary to it are declared void; copies of it are ordered to be sent to all cathedral churches, and read twice a year to the people; and sentence of excommunication is directed to be as constantly denounced against all those that by word, deed, or counsel, act contrary thereto, or in any degree infringe it. Sir Edward Coke observes, that it was confirmed no less than thirty-two times, from the

first Edward to Henry IV. Then, after a long interval, by the Petition of Right, by many salutary laws, particularly the Habeas Corpus act of Charles II. by the Bill of Rights, and lastly by the Act of Settlement.

The Magna Charta is the basis of the English laws and liberties: besides those provisions, which redressed many grievances incident to feudal tenures, care was also taken therein to protect the subject against other oppressions, frequently arising from unreasonable amercedments, from illegal distresses, or other process for debts or services due to the crown, and from the tyrannical abuse of the prerogative of purveyance, and pre-emption. It fixed the forfeiture of lands for felony in the same manner as it still remains; prohibited for the future the grants of exclusive fisheries, and the erection of new bridges, so as to oppress the neighbourhood. With respect to private right, it established the testamentary power of the subject over part of his personal estate, the rest being distributed among his wife and children; it laid down the law of dower, as it continued ever since; and prohibited the appeals of women, unless for the death of their husbands. In matters of public police and national concern, it enjoined a uniformity of weights and measures; gave new encouragement to commerce, by the protection of merchant-strangers; and forbade the alienation of lands in mortmain. With regard to the administration of justice; besides prohibiting all denials or delays of it, it fixed the court of common pleas at Westminster, that the suitors might no longer be harassed with following the king's person in all his progresses; and at the same time brought the trials of issues home to the very doors of the freeholders, by directing assizes to be taken in the proper counties, and establishing annual circuits; it also corrected some abuses then incident to the trials by wager of law and of battle; directed the regular awarding of inquest for life or member; prohibited the king's inferior ministers from holding pleas of the crown, or trying any criminal charge, whereby many forfeitures might otherwise have unjustly accrued to the exchequer; and regulated the time and place of holding the inferior tribunals of justice, the county-court, sheriff's torn, and court-leet. It confirmed and established the liberties of the city of London, and all other cities, boroughs, towns, and ports of the kingdom. And lastly, (which alone would have merited the title that it bears of the *Great Charter*) it protected every individual of the nation in the free enjoyment of his life, his liberty, and his property, unless declared to be forfeited by the judgment of his peers or the law of the land. Blackst. Comm. vol. iv.

MAGNAN-LAVAL, in *Geography*, a town of France, in the department of the Upper Vienne, and chief place of a canton, in the district of Bellac; 24 miles N. of Limoges. The place contains 2654, and the canton 6759 inhabitants, on a territory of 162½ kilometres, in five communes.

MAGNANINA, in *Ornithology*, the name of a small bird described by Aldrovand, Geiner, and some other authors, and seeming to be the same with our hedge-sparrow, commonly known among authors by the name of *curruca*. See *MOTACILLA modularis*.

MAGNANO, in *Geography*, a town of the duchy of Piacenza; 13 miles S.S.E. of Piacenza.

MAGNENTIUS, MAGNUS, in *Biography*, a German by birth, but who, from being a private soldier, rose to the chief employments in the Roman empire. He owed his distinguished station to the circumstance of his having been made a prisoner of war. To free himself from chains he joined the Roman troops, and became distinguished for valour. He was commander of the Jovian and Herculean bands, stationed to guard the banks of the Rhine, at the
time

time when Constant I. emperor of the West, had incurred the contempt of the army on account of his indolence and voluptuousness. In 350, he ascended the throne, and on the murder of Constant, he was left without a rival in the Gallic and Italian præfectures. At Rome, Magnentius acted with great tyranny, and by his various extortions, he was enabled to levy a very powerful army to maintain his usurped authority. So formidable did he appear, that Constantius, emperor of the East, and brother of the deceased Constant, fought a peace, on the terms of leaving him in possession of Gaul, Spain, and Britain, but his proposals were rejected. Constantius now determined to attack him; a bloody battle ensued, which terminated in the total defeat of Magnentius. He fled to the foot of the Julian alps, and collected the scattered remains of his army, posted them advantageously to defend the passes, and spent the winter in Aquileia. After this he went to Gaul, and obtained a victory over the van of the pursuing enemy at Pavia. His troops, however, soon sustained another defeat, after which he took refuge in Lyons, where he dispatched himself with his own sword. This event took place in the year 353, after a reign of nearly four years. The example of suicide was imitated by Decentius, who strangled himself on the news of his brother's death. A severe inquisition was extended over all who, either from choice or compulsion, had been involved in the cause of Magnentius. The most innocent people were exposed to exile and confiscation, to death and torture, and, says Gibbon, "as the timid are always cruel, the mind of Constantius was inaccessible to mercy." Gibbon.

MAGNES, in *Geography*, a town of the island of Candia, on the N. coast, supposed by Dr. Pocock to be the ancient Dictamnium, or Dictynna; 12 miles N.W. of Canca.

MAGNES Carneus, in *Natural History*, a name given by Cardan and some other authors to a white earth dug in Italy and some other places, and called also by many calamita alba. It is an indurated earthy substance of the hardness of osteocolla, and is of a white colour variegated with black lines. It adheres very firmly to the tongue, and is hence said to attract flesh in the same manner as the magnet does iron. It is even pretended, that if an iron stylus be rubbed over with this stony earth, and then plunged into the flesh, the virtue of the earth will heal the wound as soon as made, and when the weapon is taken forth, there will remain no appearance of hurt. Cardan affirms that he saw this tried with success, but suspects witchcraft in the case.

MAGNESIA, in *Agriculture*, a substance which has not yet been found in a pure state in nature; it is constantly combined either with acids in the form of earthy salts, or mixed with other earths, as *serpentine, steatites, talc, asbestos*, &c. With a view to most purposes, it is commonly prepared by the decomposition of bitter salt, by the fixed mild alkalies, and subsequent separation of the carbonic acid by calcination.

But the experiments of Mr. Tennant seem to shew, that this substance, when in combination with calcareous matters, such as that of lime, &c. is unfriendly to vegetation. It is, however, observed by lord Dundonald, that it is found "in a variety of earths and stones, and that it combines with acids, forming neutral salts, all of which are very soluble, and the greater part of them promotes, in a very considerable degree, the growth of plants. Magnesian earths, he conceives, may be applied with peculiar advantage to soils generally, and not improperly, called sour soils, containing green vitriol, arising from the decomposition of pyrites. It will decompose the metallic salt by superior affinity, and

form with the acid Epsom salt, known in a high degree to promote vegetation; while the earth of iron will be separated in the state of an ochre, or iron combined with fixable air."

It has been suggested by a writer, in the Farmer's Magazine, likewise, that he tried the vegetative power of this substance, by sowing oats in a pot containing one-tenth part of magnesia, and the rest common earth, in which they grew and thrived extremely well; but in another pot containing magnesia alone, they would not vegetate at all, which might, he thinks, be expected. It is likewise supposed to extirpate sorrel, when applied on lands that abound with it, probably by neutralizing the acid, which is the case with lime. This writer has, however, applied it to lands overgrown with sorrel, without its producing such beneficial effects.

MAGNESIA, in *Chemistry*, one of those substances that pass under the general name of earths. It is less abundant in nature than lime, alumina, or silice, but more abundant than any of the other earths. It forms a considerable part of the lime-stone, commonly called magnesian, from which it may be obtained by dissolving the stone in muriatic acid, and precipitating the magnesia with pure ammonia.

This earth was little known before its nature was investigated by the experiments of Dr. Black. It was before frequently confounded with lime.

It exists, in combination with muriatic and sulphuric acids, in sea water. The latter salt is found in some mineral waters, particularly the waters in the vicinity of Epsom, known by the name of Epsom salt.

It is from this salt that the magnesia of commerce is generally procured. The salt is first dissolved in water; then to the clear solution a quantity of common carbonate of potash is added. The magnesia is precipitated in the state of carbonate, which, when washed and dried, constitutes the magnesia commonly used in medicine. It is sometimes exposed to a strong red heat, in crucibles, by which the carbonic acid is expelled. In this state it is called calcined magnesia.

If the precipitation be made with pure ammonia instead of potash, the earth will be obtained in a state of tolerable purity.

Magnesia, in a pure state, appears in the form of powder, soft to the feel, and perfectly white. It has no taste, but when taken into the mouth it excites a peculiar sensation, arising from the rapid absorption of the saliva. It is destitute of smell, but emits a peculiar odour when moisture is applied to it. Its specific gravity, according to Kirwan, is 2.3. Like the alkalies, and the alkaline earths, it changes the blue colour of some vegetables to that of green.

It does not undergo any rapid change by exposure to the air. It slowly combines with water and carbonic acid; the former may be detected by distillation, and the latter by its effervescence with an acid.

It is nearly insoluble in water; since, according to Kirwan, it requires 7900 parts of water to dissolve one of magnesia.

Like the other earths, when strictly pure, it is not fusible at any known degree of heat, although it is capable of fusion when mixed with other earths. Lime and magnesia, in the proportion of four to one, runs through the crucible at 150° Wedgewood. But one of lime to four of magnesia did not melt at 165°. In the proportion of one of the latter to three of the former; they melted into a greenish-yellow glass. For these facts we are indebted to Kirwan.

Magnesia has long been suspected to be a compound body, but not with much ground of probability, till the late interesting experiments by Mr. (sir Humphrey) Davy, in which the alkalies and some of the earths appear to be compounds. Berzelius is said to have succeeded in decomposing magnesia by

MAGNESIA.

the agency of the Galvanic battery. The earth was placed in contact with mercury, and he supposed that the base of the magnesia, which was thought to be metallic, combined with the mercury, forming a peculiar alloy. Mr. Davy has repeated this experiment, with the sulphat of this earth, with a similar result. Attempts have since been made to decompose magnesia in various ways, by Guy Lussac and Thenard, but without any satisfactory result.

In the experiments of Mr. Davy, although he did not succeed in obtaining the metal from the alloy with mercury, he found that magnesia was produced by throwing the alloy into water. It is highly probable, therefore, that this earth, like lime and barytes, is a compound, a peculiar metal united with oxygen, between which the affinity may be so great as not to be obtained, but with great difficulty. It is, therefore, to future experiments that we must look for the final establishment of the compound nature of this earth.

It is an useful medicine for taking up acidity in the stomach; and has lately been recommended by Mr. Brandt as a solvent for the urinary calculus constituted by the uric acid.

Magnesia combines with sulphur, but very imperfectly: if two of the earth with one of sulphur be exposed to heat in a crucible, the mass becomes yellow. It affords a small quantity of sulphuretted hydrogen when thrown into water. If the heat at which it is formed be a little increased, the sulphur is expelled, leaving the earth pure. It does not combine with phosphorus, carbon, nitrogen, nor the metals, nor with any of the metallic oxyds.

There is no action between magnesia and the alkalies. The solubility of magnesia by the carbonats of the alkalies, is occasioned by the carbonic acid which leaves the alkali and combines with the earth.

Salts of Magnesia.—The greater proportion of the magnesian salts are of no known use, and have in consequence been little examined. The sulphat is the only one with which we are much acquainted, from its well known virtues as a purgative.

Sulphat of Magnesia.—This salt is found native in sea water; in the waters of Epsom, from which it has been called Epsom salt, and in many mineral waters. That used in medicine is obtained from the above sources. Several schistose stones contain sulphur and magnesia, which being exposed to air with moisture, the sulphur is converted into sulphuric acid, and, combining with the magnesia, forms this salt, which is separated from the heterogeneous matter by crystallization.

The efflorescence formed on brick walls is principally found to be sulphat of magnesia, sometimes mixed with nitre.

Sulphat of magnesia dissolves in its own weight of water at 60°. On evaporation and slow cooling, this salt crystallizes in the form of four-sided prisms; it has a bitter and disagreeable taste. The crystals have the property of double refraction. When exposed to the air they soon lose their water of crystallization, and appear in the form of white powder. When exposed to a strong heat, it first fuses in its water of crystallization, which soon escapes. If the heat be continued and raised to high temperature, it melts into a vitreous mass. It is composed, according to the analysis of Bergman, of 33 acid, 19 magnesia, and 48 water; according to Wenzel, 30.64 acid, 16.86 magnesia, and 52.5 water. Dalton makes the atom of magnesia to

be 17, that of sulphuric acid 34. Then $\frac{34 + 17}{34} = \frac{100}{67.8}$, which gives 67.8 acid, and 32.2 magnesia. If we take the

acid and base only, in the analysis of Wenzel we shall have

$$\frac{30.64 + 16.86}{36.64} = \frac{100}{64.5}, \text{ or } 64.5 \text{ acid, and } 35.5 \text{ magnesia.}$$

This salt has the property of combining with some other of the sulphats which form compounds, having peculiar properties. These, like the rest of the compounds called triple salts, perhaps in all cases, owe their existence to the circumstance of their crystallizing together, from the analogous form of their crystals, and ought not to be considered as distinct species, since on analysis they are found to consist of certain proportions of the two salts, rather than of two bases united to one common quantity of acid. There is little doubt but that these salts, when in solution, would possess the individual properties of the two salts, being in this situation a mere mixture.

The sulphat of magnesia and potash is said to be composed of three parts of sulphat of potash, and four of sulphat of magnesia. The crystals are of a rhomboidal form.

The sulphat of magnesia and soda is composed of six of sulphat of magnesia, and five of sulphat of potash. Its crystals are prismatic.

Sulphat of Magnesia and Ammonia is in the form of octahedrons, and consists of 68 of sulphat of magnesia, and 32 of sulphat of ammonia.

Nitrat of Magnesia.—This salt is formed by saturating the nitric acid with magnesia. On evaporating the solution to a certain extent, and suffering it to cool, the salt crystallizes in the form of rhomboidal prisms, which, when small, have the appearance of needles. The taste of this salt is unpleasantly bitter, like most other of the magnesian salts. It dissolves in its own weight of water at 60°; it is also soluble in nine times its weight of alcohol of the specific gravity of .84. When evaporated to dryness, and exposed to the air, it speedily becomes liquid, by attracting moisture from the air.

When exposed to a strong heat, it affords oxygen and nitrous oxyd, the acid being decomposed, leaving the earth behind in a state of purity.

Its composition by the analysis of Bergman is 43 acid, 27 magnesia, and 30 water; by Richter's, 69.6 acid, and 30.4 base; by Kirwan's, 46 acid, 22 base, and 32 water; and by Wenzel, 72 acid, and 28 base.

The weight of the atom of acid is 19, that of the base 17. Then, since the nitrats are super salts, we have

$$\frac{17 + 19 \times 2}{19 \times 2} = \frac{100}{69}, \text{ or } 69 \text{ acid, and } 31 \text{ magnesia, nearly.}$$

Muriat of Magnesia.—This salt abounds in sea water, and in some mineral waters. It may also be formed by adding carbonat of magnesia to muriatic acid, till the efflorescence ceases. When the solution is evaporated to the consistence of syrup, and exposed to a temperature of 32°, crystals of a needle shape are formed, although in small quantity and with difficulty.

It has a pungent bitter taste. It is soluble in one-half its weight of cold water, and in almost any proportion of boiling water. It is also very soluble in pure alcohol.

This salt is very deliquescent from its great attraction for moisture. In consequence of the same property, a portion of it is evaporated with the water in which it is dissolved, when exposed to a boiling heat. It is decomposable by heat, the acid being expelled.

By the analysis of Kirwan, its composition is 34.59 acid, 31.7 base, and 34.34 water. By Wenzel's, 57 acid, and 43 base. The atom of muriatic acid being 22, we have

MAGNESIA.

$\frac{22 + 17}{22} = \frac{100}{56.4}$, the acid is therefore 56.4, and 43.6 base.

The acid and base of Kirwan's analysis, reduced to the 100, will be 52 acid, and 48 base.

Hyperoxymuriat of Magnesia.—When the oxymuriatic acid gas is passed through a mixture of water and magnesia, we do not obtain an oxymuriat, but the common muriat mixed with the hyperoxymuriat. This salt has similar properties to those of the hyperoxymuriat of lime, the substance at present in use for bleaching.

Phosphat of Magnesia.—This salt may be formed by directly adding the base to the acid, as in the muriat of magnesia; or it may be formed more perfectly, by adding a solution of sulphat of magnesia to a solution of an equal weight of phosphat of soda. In a few hours, the salt in question will appear in beautiful transparent crystals.

These crystals are in the shape of hexagonal prisms, soluble in 15 parts of water at 60°. It has but little taste. When exposed to dry air, it soon loses its water of crystallization, and assumes the state of white powder. It is not decomposed by heat, but melts and becomes vitreous.

A compound salt, denominated the *phosphat of magnesia and ammonia*, has been found by Fourcroy in the calculous concretions found in the colon of the horse.

It may be prepared by mixing solutions of the two salts together. A salt of difficult solubility is precipitated. This salt is found to be an ingredient of urine, and will appear in crystals, when that fluid is exposed in close vessels for some time. It is partly from this salt that phosphorus is obtained by the distillation of urine. The ammonia is given out, leaving the phosphoric acid, which is deprived of its oxygen by the carbonaceous matter of the urine.

According to the analyses of Fourcroy and Vauquelin, it is composed of 33 phosphat of ammonia, 33 phosphat of magnesia, and 33 water.

Fluat of Magnesia.—When magnesia is added to the fluoric acid, by a little at once, it is for some time dissolved, but as it approaches saturation, it falls down in the state of white powder. This shews that the salt is soluble in excess of acid. In its neutral state, it is insoluble in water. No analysis has been given of this salt. It ought, however, to be composed in the neutral state, of 15 acid to 17 acid, or by the 100 it will be $\frac{15 + 17}{15} = \frac{100}{47}$, or 47 acid and 53 base.

Borat of Magnesia.—This salt may be formed by dissolving magnesia in boracic acid. It affords crystals by evaporation. It dissolves sparingly in water, and is soluble in acetic acid. Alcohol is said to dissolve the boracic acid from it, while the earth falls down. This salt is found native in Germany. It has the property of becoming electrical by heat; the truncated angles being plus, and the opposite ones minus.

Carbonat of Magnesia.—This salt may be formed by adding a solution of carbonat of potash to sulphat of magnesia. A white powder is precipitated, which, when washed and dried, constitutes the magnesia used in medicine. (See CARBONAT of Magnesia.) It is slightly soluble in water, at least more so than the earth itself. If, however, the supercarbonat of potash be added to the solution of sulphat of magnesia, a supercarbonat of magnesia will be formed, which is more soluble and capable of crystallization by evaporation, their form being that of hexagonal prisms. It is said to be soluble in 48 parts of cold water, but less soluble in hot water. It is, however, in all likelihood much more

soluble when it is first formed, or when the decomposition of the sulphat takes place by the supercarbonat of potash. There appears much inconsistency in the analysis by different chemists. The carbonat by theory should consist of 19.4 acid, to 17 base, or in the 100, 53.3 acid, and 46.7 base. The supercarbonat consists of 2×19.4 acid, and 17 base. In the 100, 69.5 acid, and 30.5 magnesia.

Acetat of Magnesia.—This salt may be directly formed, by dissolving magnesia in the acetic acid. It does not crystallize when evaporated to dryness, it soon attracts moisture from the air. It is very soluble both in water and alcohol.

Its component parts, according to Richter, are 70.65 acid, and 29.35 base.

Oxalat of Magnesia.—This salt is nearly insoluble in water as well as alcohol.

Tartrat of Magnesia.—The tartaric acid dissolves magnesia, forming a salt which crystallizes in needles.

Citrat of Magnesia.—This salt may be formed like the last, by adding the base to the acid. It does not afford crystals. It is composed of 66.66 acid, and 33.34 base.

Malat of Magnesia is a deliquescent salt.

Camphorat of Magnesia.—When magnesia is boiled with crystals of camphoric acid in water, they unite, forming a salt, which, on evaporation and cooling, falls down in small scales. The rest of the magnesian salts are not known to be of any importance.

MAGNESIA ALBA, P. L. 1787, *Magnesia Carbonas*, or *Carbonate of Magnesia*, in the *Materia Medica*, a fine white powder, which formerly at Rome bore the name of the Count of Palma; though many are of opinion, that the preparation was carried from Germany into Italy. It was, however, for several years, a celebrated secret, in possession of some particular persons, till the method of preparing it was made public by Lancisi in the year 1717, and afterwards by Hoffman in 1722. It was then extracted from the mother-ley, or the liquor which remains after the crystallization of rough nitre; either by precipitation with a solution of fixed alkaline salt, or by evaporating the liquor, and calcining the dry residue, so as to dissipate the acids by which the earth had been made dissoluble. As quicklime is commonly much employed in most of the German, French, and other European nitre-works, the substance obtained from the mother-leys of those works is rather a calcareous earth than magnesia, and appears to be such by its burning into quicklime, and forming a selenites with the vitriolic acid. Magnesia was called the *miraculum chemicum*, because from two pelucid liquors a coagulum is formed, which contains this substance.

From the experiments of Dr. Black, related in the *Edinburgh Phyl. and Lit. Est.* vol. ii. art. 8. we learn, that magnesia is soluble, with effervescence, in vitriolic, nitrous, marine, and acetic acids; forming, with the vitriolic acid, crystals similar to those of the Epsom salt, and with the nitrous acids, crystals which deliquesced in a moist air: with marine acid it formed no crystals; but the saline matter being evaporated to dryness, soon deliquesced by exposure to air: with distilled vinegar it formed no crystals by evaporation, but a saline mass, viscid when warm, resembling glue in colour and consistence, and brittle when cold. Magnesia was found to lose, by calcination, seven-twelfths of its weight, and was thus deprived of the power of effervescing with acids; whence the substance lost by calcination was gas, or fixable air: nevertheless this gas, and almost the whole weight lost by calcination, were restored to it by solution in vitriolic acid, and precipitation from them by a mild fixed alkali, the gas of which it absorbed: in this last respect

MAGNESIA.

ipeet it seemed analogous to the calcareous earths, but differed from them in other properties; particularly in these, that when calcined, it was not soluble in water, nor communicated any sensible impregnation to it, and that it did not, like them, when calcined, become caustic or acrid.

Dr. Black also found, that magnesia was precipitated from acids by volatile alkali; that, when uncalcined, it precipitated calcareous earth from acids; but when calcined, or in any other way deprived of its gas, it did not precipitate these earths: when uncalcined or united with gas, it precipitated lime from lime-water; which shews that the calcareous earth had a stronger power to combine with the gas, than the magnesia had, since the former earth took this gas from the latter; by which means the former was rendered mild and unsoluble in water, and therefore was precipitated. This property suggested to Dr. Allston a method of procuring sweet water at sea, by adding magnesia to water, the putrefaction of which has been prevented by the previous addition of quick-lime. M. Monnet observes, that magnesia, combined with sulphur, generally envelopes strata of coal: M. Margraaf has discovered that the serpentine earths in Saxony contain magnesia: and M. Monnet adds, that the marly and also the alum earths contain it.

The directions for preparing it, given in the last London Pharmacopeia, are as follow: Take of sulphat of magnesia, subcarbonat of potash, of each a pound, and water three gallons. Dissolve the subcarbonat of potash in three pints of the water, and strain; dissolve also the sulphat of magnesia separately in five pints of the water, and strain: then add the rest of the water to the latter solution; apply heat, and when it boils, pour in the former solution, stirring them well together; next strain through a linen cloth; lastly, wash the powder repeatedly with boiling water, and dry it upon bibulous paper in a heat of 200°. The double decomposition of the salts used in this process yields carbonat of magnesia and sulphat of potash, the first of which it is the object to collect as free as possible from the last. Hence, as the newly formed sulphat of potash requires a large proportion of water for its solution, such a proportion is directed in the first instance, and it is afterwards well washed with more. If water be impregnated with carbonic acid gas, it will dissolve carbonat of magnesia; and hence the liquor is made to boil, for the purpose of detaching it. If the two solutions be mixed cold, and the precipitate left for some days upon the filter without artificial drying, many large and perfect crystals of carbonat of magnesia will be formed in it. The subsequent heat, by which the powder is dried, should not be great enough to detach any of the carbonic acid. The present process will yield a pure and elegant preparation: its form is that of a white powder, easily friable, and, according to Fourcroy, if the base be fully saturated with carbonic acid, as in the crystals, (for in its ordinary form it is a subcarbonat,) 100 parts contain of carbonic acid 50, of magnesia 25, of water 25; and if not so saturated, but in its state of sub-salt, of carbonic acid 48, of magnesia 40, and of water 12. In commerce, the muriat of magnesia contained in the residuary liquor, after the crystallization of soda from sea-water, is decomposed by a similar process, and yields a large proportion of the ordinary magnesia of the markets. The dose of carbonat of magnesia to adults is from ʒss to ʒii, and of sulphat from ʒi to ʒi. See *CARBONAT of Magnesia*, and the preceding article.

Mr. Henry, an ingenious apothecary at Manchester, has communicated the following process for making the magnesia. Dissolve any quantity of sal catharticus anarus in its own weight of water; filter and add to it by degrees a fil-

tered solution of pearl or pot-ashes, in an equal quantity of water, stirring them gently, until the mixed liquors have acquired the appearance of a complete coagulum; then desist from adding any more of the alkaline lixivium, and immediately throw the mixture into a large vessel of boiling water; keep it boiling for a quarter of an hour, then take it out, and put it into glazed earthen vessels; as soon as the powder hath subsided, and before the water is quite cold, pour it off, and add a fresh quantity of boiling water; repeat these ablutions with hot water several times, till the liquor hath entirely lost its saline taste: then let it be so agitated as to suspend the finer parts of the powder, in which state decant it into other vessels, and having separated the water from the magnesia, by inclination, put it on large chalk-stones, till a considerable part of the humidity is absorbed; then wrap it up in sheets of white paper, and dry it before the fire. Pour hot water upon the remaining powder, stir and decant it in its turbid state, and separate the magnesia from the water as before: thus the whole, or most of it, will be reduced to an equal degree of fineness. The larger the quantity of water into which the precipitated powder is cast, the more speedily and perfectly will the vitriolated tartar, which is formed by the union of the alkali with the acid of the sal. cath. be washed off. The neutral salt should be washed off as quickly as possible; otherwise, by allowing the mixture to stand for some time, the powder concretes into minute grains, which, when viewed with a microscope, appear to be assemblages of needles diverging from a point. These concretions cannot be re-dissolved by any washing, however long continued. Dr. Black orders four times the quantity of water to that of the solution for throwing the coagulum into; but Mr. Henry observes, that this quantity is much too little. The water should be pure, and distilled water is the best, provided it be kept till its empyreuma is gone off. Hard or impure water makes magnesia coarse and disagreeable. The chalk-stones on which the magnesia is dried should be exposed to a moderate heat, that the moisture may evaporate quickly: and cleanliness should be particularly attended to through the whole process.

The magnesia is recommended by Hoffman, as an useful antacid, a safe and inoffensive laxative in doses of a dram or two, and a diaphoretic and diuretic, when given in smaller doses of fifteen or twenty grains. It is now much in use, particularly in heart-burns, for correcting acidities in the primæ viæ, and for preventing or removing the many disorders to which children are subject on this account. It is preferred to all common absorbents, on account of its laxative quality, which it manifests when it meets with an acid in the stomach and bowels. If it is mixed with rhubarb, it prevents the rhubarb from leaving a costiveness behind. If the magnesia is neither accompanied, nor met with by an acid, it is not purgative, but simply absorbent.

Objection has been made to the use of magnesia by Hoffman and others, that it frequently produced flatulencies, gripings, and other uneasy sensations, particularly in weak bowels. It is now well known, that these symptoms must have been produced by the great quantity of fixed air contained in it, and discharged from it in consequence of its meeting and effervescing with an acid in the stomach or intestines. Dr. Percival, therefore, suggested to Mr. Henry the idea of depriving it of its air, with a view of obviating these troublesome symptoms occasionally attending the use of it. For this purpose the magnesia should be calcined by putting it in a common crucible, placing it in a glowing fire, and keeping it red-hot for the space of two hours. The magnesia thus treated was found to be equally purgative,

tive, when given in half its former dose, and is deprived, by this process, of the disagreeable qualities above mentioned, and acquires likewise new properties, which render it likely to answer some other important practical purpose. By calcination it is not only rendered incapable of generating air in the stomach and bowels, but it is qualified to absorb, or render fixed, that which it finds there, and which is produced, sometimes in too great quantities, in the process of digestion; and it is consequently adapted to relieve those colics or other disorders, which are commonly called flatulent. In this respect it promises, as Mr. Henry observes, to be much more efficacious than the whole tribe of carminatives, from which it essentially differs with regard to its mode of operation and effects. It appears likewise to be the most proper cathartic for patients afflicted with the stone, who are under a course of the soap-ley; as it cannot, like the vegetable purgatives, counteract the lixivium, by throwing air into it; but, on the contrary, must absorb a part of that air, which is already in the primæ viæ, and which would otherwise be attracted by the caustic alkali, and render it less capable of acting on the calculus. In order to produce these effects, it is of great importance that the magnesia, intended for calcination, should be perfectly free from any admixture of calcareous earth; as in that process, this last mentioned substance must necessarily be deprived of its air, or rendered caustic; and the magnesia which contains it will accordingly impregnate the water in which it is infused with the taste and qualities of lime-water. Mr. Glaß's magnesia, which has been so highly extolled, appears, by Mr. Henry's experiments, to contain no inconsiderable portion of calcareous earth. Lond. Med. Transf. vol. ii. art. 16. Henry's Exp. and Obs. 1773.

MAGNESIA *Nigra*, in *Chemistry*. See MANGANESE.

MAGNESIA, *Opalina*, *Opalina*, or ruby-coloured magnesia of antimony, is made, according to the directions of Lemery, of equal parts of antimony, nitre, and decrepitated sea-salt. It is a much weaker emetic than the liver of antimony.

MAGNESIA *Usta*, P. L. 1787, *Magnesia*, in the *Materia Medica*, is prepared by burning four ounces of carbonate of magnesia in a very strong fire, for two hours, or until acetic acid, being dropped in, extricates no bubbles of gas. Here it may be noted that a definite quantity has been prescribed merely for the sake of precision, and not as influencing the quality of the product. This preparation was the "magnesia usta" of the former Pharmacopœia; but as the term "magnesia" is correctly used to express only the pure earth, so it has been thought proper to apply it decidedly in the present instance, although in common language, the same term may be most generally applied to the carbonate, and the epithet *calcined* added to express the present preparation. The process depends upon the expulsion of the carbonic acid of the carbonate by heat, and in the form of gas, and hence the carbonate yields about half its weight, or rather $\frac{2}{3}$ ths of the pure magnesia. It may be considered as insoluble in water; for Kirwan states 7900 times its weight to be necessary for this purpose at 60°. The dose of magnesia for adults is from ʒss to ʒj.

MAGNESIA, in *Ancient Geography*, a province situated on a peninsula E. of Thessaly, and S.E. of Macedonia; which some geographers have annexed to the former country, and others have described as part of the latter. Strabo and Pliny place this province in Macedonia, and in their time the Romans had annexed it to this country; but before the kings of Macedonia had extended their conquests beyond mount Olympus, Magnesia was reckoned a portion of Thessaly.

It had been denominated *Æneonia* and also *Magnes campus*. The peninsula on which it was situated bounded on the S.W. the Sinus Pelasgiacus, the entrance of which formed a strait, having on the N.E. the *Æantium promontorium* in Magnesia, and to the S.W. the *Antron* in Phthiotis. Magnesia extended as far as mount Ossa, and as some say, to the valley of Tempé; and M. d'Anville places to the N.W. of it, the country called Pelasgiotis. In Magnesia were found the following towns, viz. Magnesia, Phera now Sidero, Jerusaf or Fanisar, Melibœa parva, Ilcos, Demetrias now Demetriada, Pagasæ, and Tempe Thessala. Its mountains were Ossa now Cossovo, and Pelion, and its promontories were those of Magnesia and Sepias.

MAGNESIA, the capital of the above province, situated on the eastern coast, at the bottom of a small gulf.

MAGNESIA *ad Mœandrum*, a town of Asia Minor, in Ionia, on the northern bank of the Mæander; 15 miles S.E. of Ephesus. This, according to Diodorus Siculus, was one of those towns given by Artaxerxes to Themistocles. According to Pliny, this town was a colony of Magnesian of Thessaly, united with the Cretans. The Turks call it "Guzel-Hisar," or the beautiful castle.

MAGNESIA *ad Sipylum*, or *Magnesia Sipylæ*, a town of Asia Minor, in Lydia, at the foot of mount Sipylus, S. of the confluence of the rivers Hyllus or Phrygius, and the Hæmus. The victory obtained by the Romans over Antiochus, near this city, rendered it famous. Strabo says, that under the reign of Tiberius, it was destroyed by an earthquake. Near it was a beautiful plain of the same name, at the foot of mount Sipylus.

MAGNESITE, *Native Magnesia*; *Native Talk Earth*, Jam.; *Reine* or *Natürliche Talk-erde*, Wern.; *Magnésit*, Karsten; *Magnésite native*, Broch.; *Magnésite de Mitchell*, Brongn.; *Magnésite carbonatée*, Haüy.

The following description is derived from the original native magnesia of Dr. Mitchell, and that of Piemont described by Giobert. All the others we find mentioned by authors are dubious.

Colour yellowish-grey, or a dirty-yellowish white, that of Piemont blueish-white before it has been much exposed to the air; that of Moravia is marked with blackish-brown stains, penetrating from the surface into the interior, as also marbled with grey and blueish-grey spots.

It is always found massive, generally in rounded pieces, sometimes of the size of a man's head, and of earthy aspect: these pieces are sometimes found with fissures, but not with rounded cells.

Its hardness variable; in its more compact state the Moravian variety scratches calcareous spar, but is scratched by fluor spar; the most compact Piedmontese varieties are still harder. It is also found in a friable state, when it soils the fingers.

Fracture flat conchoidal, approaching to even; dull.

Its tenacity is inconsiderable, especially in those varieties that contain no silica.

Fragments indeterminately angular, more or less sharp-edged.

It is generally perfectly opaque; sometimes very thin fragments are translucent at the edges.

It is scarcely at all unctuous to the feel. It adheres to the tongue.

Specific gravity of the whitish variety from Moravia, when penetrated by water, 2.881, and when not thoroughly saturated with it, 2.456; Haberle.

Magnésite is perfectly infusible before the blowpipe. In a strong heat it loses its carbonic acid; contracts and acquires a sufficient

M A G

a sufficient degree of hardness to scratch glass. It dissolves with effervescence in concentrated acids; but Giobert informs us that the variety of Castellamonte contains no carbonic acid when in the bosom of the earth; whence, as in all other respects it is like the magnesia from Baudisfero, he is of opinion that also the latter is originally destitute of carbonic acid, and that it only contains it, when, after a long exposure to contact with the air, it can absorb it from the atmosphere.

The following are the results of the analyses that have been lately given of the different varieties of this substance. Those of Hrubshitz, in Moravia, according to the experiments of the accurate Bucholz, contain

Variety I.

Magnesia	-	0.48
Carbonic acid		0.52
		<hr/>
		100
		<hr/>

Variety II.

Magnesia	-	46.59
Carbonic acid		51.
Alumine	-	1.
Oxyd of iron and manganese	} 0.25	
Lime	-	0.16
Water	-	1.
		<hr/>
		100.
		<hr/>

Variety III.

Magnesia	-	45.42
Carbonic acid		47.
Silica	-	4.50
Water	-	2.
Alumine	-	0.50
Oxyd of iron and manganese	} 0.50	
Lime	-	0.08
		<hr/>
		100.
		<hr/>

100. Ann. de Chem. tome 74.

The analyses that were first given by Mitchell, Lampadius, and Klaproth, of the Moravian magnesite, agree pretty exactly with those of Bucholz, but they all differ considerably from that published by Wondrascheck, who obtained magnesia 33, carbonic acid 30, silica 8, lime 0.5, manganese and iron 1.5, water 20, loss 7.

Giobert and Guyton's analyses of the Piemontese magnesite again offer different results. That of Baudisfero contained in hundred parts

Magnesia	-	68.
Carbonic acid		12.
Silica	-	15.6
Sulphate of lime		1.6
Water	-	3.
		<hr/>
		100.2
		<hr/>

Giobert.

And that of Castellamonte

The two known localities of magnesite are Hrubshitz district of Gromau, in Moravia; and Baudisfero and Castellamonte, villages in the vicinity of Turin. The Moravian variety was brought by Dr. Mitchell from Vienna, and presented to Werner, who gave it its present place in the system. The Piemontese varieties passed a long time for pure alumine, till Giobert discovered their true nature.

The geognostic situation of this fossil in either of the above countries, is nearly the same. At Hrubshitz it is found in a bed of decomposing serpentine; accompanied with common and earthy talc, meerschaum, and magnesian limestone. That of Turin occurs in a similar serpentine rock, accompanied, according to Giobert, by hornstone in decomposition, to which latter this chemist is inclined to ascribe the origin of the magnesite.

According to Giobert, the magnesite of Baudisfero forms an excellent porcelain with flux. He also made crucibles and capsules of it, having added some of the argillaceous earth of Castellamonte, sufficient to unite it into a paste. The crucibles were exposed for 48 hours in the furnace of a glass house; the earths did not appear to have formed a sufficient union; nevertheless, the hardness of the crucibles was such that they could not be affected by the file.

It may also be employed with advantage for producing sulphat of magnesia by means of sulphat of iron, which likewise abounds in the same places of Piemont.

MAGNET, MAGNES, the *Loadstone*; a sort of ferruginous stone, in weight and colour resembling iron ore, hard, so as just to afford sparks when struck with steel, and heavy; endowed with divers extraordinary properties, attractive, directive, inclinatory, &c.

The magnet is also called *lapis Heracleus*, from Heraclea, a city of Magnesia, a part of the ancient Lydia, where it is said to have been first found, and from which it is usually supposed to have taken its name. Though others derive the word from a shepherd named *Magnes*, who first discovered it with the iron of his crook on mount Ida. It is also called *lapis nauticus*, by reason of its use in navigation; and *siderites*, from its attracting iron, which the Greeks called *σίδερος*.

The magnet is indeed a true iron ore, from which a considerable portion of iron may be extracted, and is usually found in iron mines, and sometimes in very large pieces, half magnet, half common ore. This species of iron ore contains a greater quantity of iron, either in the metallic state, or not much oxygenated, than most other ores. Nevertheless, though every magnet seems to contain some iron in a metallic state, it does not follow that every kind of ore, which contains iron in that state, is magnetic: many iron ores having been found, which had the appearance of being good magnets, and yet were not possessed of the magnetic properties. The natural magnets often contain, besides particles of iron, a portion of quartz and argil, and probably some sulphur; whence they have, when made red hot, a sulphureous smell; and also some other substances. Magnets differ with regard to their specific gravity, according to the nature and proportion of the other ingredients which are

M A G N E T.

mixed with the iron or martial part; but they are generally about seven times heavier than distilled water. The colour of the magnet is different, white, blue, red, black, but mostly ferruginous, or a dull brownish-black, according to the different countries it is brought from, the admixture of heterogeneous substances, and the state of the iron contained in them. Norman observes, that the best are those brought from China and Bengal, which are of an iron or sanguine colour; those of Arabia are reddish; those of Macedonia blackish; and those of Hungary, Germany, England, &c. of the colour of unwrought iron. Neither its figure nor bulk is determined, but it is found of all forms and sizes.

It has been observed, that, in general, those magnets which have a fine close grain, are more powerfully magnetic, and retain the virtue much longer than those that are of a coarser grain; and even longer than the artificial magnets which are made of steel.

The ancients reckoned five kinds of magnets, different in colour and virtue; the Ethiopic, Magnesian, Bœotic, Alexandrian, and Natolian. They also took it to be of two kinds, male and female; but the chief use they made of it was in medicine; especially for the cure of burns, and defluxions on the eyes. The moderns, more enlightened and happy, take it to conduct them in their voyages.

As the properties possessed by the natural magnet may be communicated to iron, steel, and other ferruginous substances, these bodies, after having acquired the magnetical properties, are called *Artificial MAGNETS*; which see.

The most distinguishing properties of the magnet, whether natural or artificial, are, that it attracts iron, and other ferruginous substances, thus serving the purposes of the chemist in discovering or separating small particles of iron, mixed with other matters; and that it points towards the poles of the world; that it is endued in certain cases with attractive and repelling powers; and in other circumstances, also dips or inclines to a point beneath the horizon, directly under the pole; and that it communicates these properties, by proper methods, to iron, steel, and other ferruginous substances. On which foundation are formed the mariner's needles; both the horizontal, and the inclinatory, or dipping-needles.

MAGNET, the attractive Power of the was known to the ancients, and is mentioned even by Homer, Pythagoras, Aristotle, and by Plato and Euripides, who call it the *Herculean stone*; because it commands iron, which subdues every thing else. The Jews were acquainted with it. This property is finely described by Pliny: "Quid lapidis rigore pigrus? Ecce sensus manusque tribuit illi. Quid ferri duritia pugnacius? Sed cedit, et patitur mores: trahitur namque a magnete lapide, domitrixque illa rerum omnium materia ad inane nescio quid currit; atque ut proprius venit, assidit teneturque, complexaque hæret." Lib. xxxvi. cap. 16.

The ancients seem also to have been acquainted with the communicative virtue of the magnet. Plato has described a chain of iron rings suspended by one another, the first of which is sustained by the load-stone: Lucretius, Philo, Pliny, Galen, and Nemelius, have likewise described the same phenomenon; but the knowledge of its directive power, whereby it disposes its poles along the meridian of every place, and occasions needles, pieces of iron, &c. touched with it, to point nearly north and south, is of a much later date; though the exact time of its discovery, and the discoverer himself, are yet in the dark. The first tidings we hear of it are erroneously referred to the year 1260, when Marco Polo, the Venetian, is said by some to have introduced the mariner's compass (see *COMPASS*); though not as an invention of his own, but as derived from the Chinese, who are said to have had the use of it long before; though some ima-

gine that the Chinese before that had borrowed it from the Europeans. Flavio de Gioia, a Neapolitan, and a citizen of Amalfi, is the person usually supposed to have the best title to the discovery, about the year 1302, and he, if not the inventor, was the first who used it for the guidance of vessels in the Mediterranean; and yet Sir G. Wheeler mentions that he had seen a book of astronomy much older, which spoke of the use of the needle: though not as applied to the uses of navigation, but of astronomy. And in Guyot de Provins, an old French poet, who wrote about the year 1180, there is express mention made of the load-stone and the compass, and their use in navigation is obliquely hinted at. The Spanish Jesuit Pineda and Kircher affirm, that Solomon knew the use of the compass, and that his subjects did actually use it in their navigation. See *COMPASS, Mariner's*.

It appears from a Latin letter, written by Peter Adfiger, on the description of the nature of a magnet, and dated in 1269, from which Mr. Cavallo has made copious extracts in his "Treatise on Magnetism," 1800, that most of the properties of the magnet, with which we are now acquainted, were known in his time; though they were not applied to the same useful purposes. From these extracts we learn that the laws of magnetic attraction, and of the communication of that power to iron, the directive property of the natural magnet, as well as of the iron that has been touched by it, and even the declination of the magnetic needle, were particularly described by Adfiger with a view to the instruction of a friend. See *Mariner's COMPASS*.

MAGNET, Variation of the, or its declination from the pole, is said to have been first discovered by Seb. Cabot, a Venetian, in 1500, who first served our king Henry VII. then the king of Spain, and lastly returning to England, was constituted grand pilot by king Edward VI. with an annual salary of above 160*l.*; though Ferdinand, the son of Columbus, asserts that his father observed it on the 14th of September, 1492: and the variation of that variation by Mr. Gellibrand, an Englishman, who published his discovery in a small quarto pamphlet, intitled "A Discourse Mathematical on the Variation of the Magnetic Needle," printed in 1635. See the preceding article, and *DECLINATION*.

Lastly, the dip or inclination of the needle, when at liberty to play vertically, to a point beneath the horizon, was first discovered by another of our countrymen, Mr. R. Norman, who, in 1581, published the discovery he had long before made, in a small pamphlet, called the "New Attractive," where he shews how to determine its quantity. See *DIPPING and DIPPING-needle*.

MAGNET, Phenomena of the. 1. In every magnet there are at least two poles, one whereof points northward, the other southward; one of these is called the north pole, and the other the south, and that is called the north pole, which, if the magnet was put into a little boat of wood, or other materials large enough to support it, and set afloat in water, or so suspended by a thread, &c. as to be at liberty to move itself easily, would turn itself towards the north pole of the earth, or towards a point not much distant from it; and that is called the south pole which would turn, in similar circumstances, towards the south. The property itself is called the magnet's "directive power," or "magnetic polarity;" and when a magnetic body places itself in that direction, it is said to "traverse." A plane perpendicular to the horizon, and passing through the poles of a magnet when standing in their natural direction, is called the "magnetic meridian;" and the angle made by the magnetic meridian and the plane of the meridian of the place where the magnet stands, is called the "declination of the magnet," or more commonly the

M A G N E T.

“declination of the magnetic needle;” because the artificial magnets, commonly used for observing this property, are generally made slender, and somewhat in the shape of a needle, or because real sewing needles have been often used for this purpose. The north pole of one magnet always attracts the south pole, when placed opposite to one another, and repels the north-pole of another, and *vice versa*. In short, magnetic poles of the same name repel one another, whereas those of a different name attract one another. It is observed that the poles of magnets are not at their extremities, but at a little distance from thence; and if the magnet be divided into ever so many pieces, the two poles will be found in each piece, and sometimes more than two; though each of the parts has not always the same number of poles. The poles of the fragments generally, but not always, answer to the poles which were nearest to them in the original magnet. We may add, that in some natural magnets there are more than two poles, instances having occurred of some in which there are eight, nine, and even ten. M. Muschenbroek says that he has seen a cube, each side of which was polar. The figure, and also the heterogeneous nature of the magnets, are the principal causes of their having often more than two poles. In order to determine the number and situation of the poles in a magnet, let the various parts of its surface be presented to one of the poles of another magnet that is freely suspended; then those parts of the magnet which repel the other that is suspended, have the same polarity, and those which attract it have a different polarity. *E. G.* If the magnet be presented to the north pole of the other suspended magnet, then those parts of the former which repel the latter are possessed of a north polarity, and those which attract it are possessed of a south polarity.

By the following method also, the situation of the poles, and the direction of the (supposed) magnetic effluvia in passing out of the stone, may be exhibited to the sight: let *A B, C D*, (*Plate VI. Magnetism, fig. 1.*) be the poles of the stone; about every side gently strew some iron or steel-filings on a sheet of white paper; these small particles will be affected by the effluvia of the stone, and so disposed as to shew the course and direction of the magnetic particles in every part. Thus, in the middle of each pole between *A B* and *D C*, it appears to go nearly straight on; towards the sides it proceeds in lines more and more curved, till at last the curve lines from both poles exactly meeting and coinciding form numberless curves on each side, nearly of a circular figure, as represented in the diagram.

A small artificial magnet may be used in this experiment instead of the real magnet, with a similar effect. If the table on which the paper rests receives a few gentle knocks, so as to shake the filings a little, they will the more readily dispose themselves round the magnetic bar; otherwise, the action of the magnet will not have power sufficient to dispose properly those particles which lie at a considerable distance. This phenomenon, which has been observed from time immemorial, has led various persons to believe, that a certain fluid circulates from one of the poles of every magnet to the other, in consequence of which the iron or steel-filings are thus arranged round the magnet. A little consideration will evince the absurdity of this supposed circulation, because if the fluid, of whatever nature it may be, did really circulate from one pole to the other, and had any action on the filings, these would be all driven toward that pole to which the moving fluid directed its course. The true cause of the arrangement of the filings is, their becoming actually magnetic, and their two extremities being possessed of different polarities. Suppose, first, that only one oblong particle of iron be affixed to the various parts of

the surface of the magnet, it is evident, from what has been already said, that on the poles this particle of iron, *A B*, (*Plate VI. Magnetism, fig. 2.*) would stand perpendicular to the surface, because its farther extremity *B*, having the same polarity as the extremity, *C*, of the magnet, is equally repelled by it on every side, and is far from the influence of the other extremity *D*; on the sides near to the poles the said particle will stand inclined, because the farthest pole of the magnet begins now to act upon it; and on the middle of the magnet the wire will lie quite close to it, or, if it be kept at some distance, will lie parallel to the magnet, because the two poles of the magnet, being equidistant from the extremities of the iron particle, have an equal action upon it. Now, when there are many particles of iron, *viz.* the filings, near the magnet, those particles which touch its surface are rendered magnetic, consequently they attract other particles, and these being made also magnetic, attract others, and so on; forming strings of small magnets, which gradually decrease in power as they recede from the magnet. As each of these particles has two magnetic poles, by a little consideration it will appear, that the farthest ends of those strings or lines which proceed from the parts adjacent to one of the poles of the magnet, for instance, the north, are likewise possessed of the north polarity, and the farthest extremities of those strings which proceed from the parts adjacent to the south pole of the magnet, are possessed of the south polarity; hence, when they come sufficiently near, they attract the extremities of the former strings, and consequently form the curves delineated on the figure.

The situation of the poles may be also determined by placing over the magnet a very fine needle, which will stand perpendicular over each pole, being more strongly attracted by it, and no where else.

When a magnet that is freely suspended, has only two poles, it will place itself very readily in the magnetic meridian, or in that place in which other good magnets are wont to place themselves; but when it has more than two poles, it may happen that these poles are so situated, as that the magnet will not traverse; that is, it will have no directive power, and yet it will attract, repel, &c.

Two circumstances deserve to be noticed with respect to magnets that have more than two poles. One is, that the parts adjacent to one pole are possessed of a contrary polarity; and the other is, that the number of poles of one denomination in a magnet is either equal to, or differs from, the number of poles of the other denomination by one; thus, if the magnet has four south poles, then it will have either four, three, or five north poles. It is observed, that good magnets of an uniform texture and proper form, have only two poles, and they lie in opposite parts of their surfaces, so that a line drawn from the one to the other passes through the centre of the magnet. The polarity of a magnet, however, must not be understood to reside only in two points of it; for, in reality, it is the half, or a great part of the magnet that is possessed of one polarity, *i. e.* has the property of repelling the contrary pole of another magnet; and the rest of the magnet is possessed of the other polarity; the poles being, therefore, those points in which that power is the strongest.

In magnets, such as we have just described, the line between the two poles is called the “axis;” and a line formed all round the surface of the magnet by a plane, which divides the axis into two equal parts, and is perpendicular to it, is called the “equator of the magnet.” Hence it appears, that philosophers have appropriated to the magnet the poles, the equator, the meridian, in imitation of the terraqueous globe; and to complete the similarity, magnets have been

often

M A G N E T.

often made of a spherical shape, with the poles and the equator marked on their surfaces. When so shaped, they have been called "terrellas," *i. e.* small earths.

The poles of any given magnetic body may be ascertained by presenting the various parts of its surface successively to one of the poles of a magnetic needle, and you will soon discover which parts of the given body are possessed of a contrary polarity, by the needle's standing perpendicularly towards them. Then present the various parts of the surface of the same body to the other pole of the needle, &c. The magnetic body, in this operation, should not be brought too near the needle, for fear of changing its polarity. The distance is various for producing such an effect, according to the strength of the magnetic body; so that it is impossible to state it; but the operator needs never mistake, if he keeps the magnetic body so far from the needle, as just to affect it sensibly.

2. These poles, in different parts of the globe, are differently inclined towards a point under the horizon. Thus, when a magnet is placed so as to be at liberty to move itself very easily, it generally inclines one of its poles towards the horizon, and of course it elevates the other above it. This property is called the "inclination" or "dipping" of the magnet, or more commonly of the "magnetic needle." See DIPPING.

3. These poles, though contrary to one another, do help mutually towards the magnet's attraction and suspension of iron.

4. If two magnets be spherical, one will turn or conform itself to the other, so as either of them would do to the earth; and after they have so conformed or turned themselves, they will endeavour to approach or join each other; but if placed in a contrary position, they will avoid each other. This property may be illustrated by placing two magnets on small pieces of wood, formed in the shape of boats, and swimming freely on stagnated water, undisturbed by wind, and at such a distance as to be within the sphere of each other's activity: both the boats will swim towards each other with an accelerated motion, and meet exactly in the middle of the distance between them, provided that the boats and magnets were exactly of the same weight and bulk: but if either boat be turned, so that its magnet may present a contrary end to that by which it was attracted by the other magnet, they will both recede from each other with an equal velocity. The same phenomenon may likewise be exhibited by suspending a magnet, C, from the end, B, of a balance (*Plate VI. Magnetism, fig. 3.*), and forming an equilibrium with a weight in the scale A, place another magnet, D, under C, and C will be found to rush towards D, and to lift the weight in the scale A: but if the opposite end of D be presented to C, C will be repelled by it, ascend, and the scale, A, will descend: if D be placed above C, as in E, the effects will be just the contrary.

M. Muschenbroeck has found by a variety of experiments, that two magnets attract one another with different forces at different distances; that they act most strongly in mutual contact, in which case their force has been equal to the weight of three hundred and forty grains, but at the distance of twelve inches, equal only to twenty-three grains: nevertheless, they observe no regular proportion in their decrease, but the ratio is less than the inverse of their distances; and different in different magnets and at different times. There are some whose sphere of activity reaches even to fourteen feet, and others in which it is not sensible at the distance of eight or nine inches. He has also found, that the sphere of repulsion varies in different magnets, and at different distances; and that the repulsive force is much

less than that of attraction; the latter in contact being equal to three hundred and forty grains, whereas the former is equal only to forty-four grains. It appears also from another experiment of the same author, that the repelling forces of both poles of the same magnet, are very considerable at the distance of twelve lines, being equal to thirty grains; that they increase to the distance only of seven lines, where they are equal to thirty-six, but that in immediate contact they are equal only to thirteen grains. Mr. Michell, however, differs much in his deductions from those above-mentioned: he maintains, that each pole acts, attracts, or repels exactly equally, at equal distances in every direction; and that the magnetical attraction and repulsion are exactly equal to each other. He adds, that the mistake of those who think otherwise, arose from their not attending to the different degrees of strength, which magnets have in different circumstances: for two magnets that are placed with their attracting poles towards each other, will have their power, by that means, increased: and on the contrary, if their repelling poles be placed towards each other, their power will thereby be diminished: and this increase or diminution of power will be in a greater or less degree, according as the magnets are nearer to, or farther from, each other; whence in all the experiments made on this subject, the attraction and repulsion come perpetually nearer to an equality, the greater the distance of the two magnets is, with which the experiments are made, and *vice versa*.

And so great is the effect of magnets on each other, that when the repellent poles of a large magnet and a small one are brought into contact, the small one shall sometimes have its repellency changed into attraction. Mr. Michell also infers from other experiments, that the attraction and repulsion of magnets decrease as the squares of the distances from the respective poles increase. The differences of opinion in this respect are ascribed by him to the want of making proper allowances for that property of magnets, in consequence of which they attract or repel equally at equal distances, together with the increase and diminution of power in the magnets with which the experiments were tried.

We shall here subjoin a few more observations on magnetic attraction and repulsion. If a piece of iron, or steel, or other ferruginous substance, be brought within a certain distance of one of the poles of a magnet, it is attracted by it so as to adhere to it with a considerable degree of force; and this attraction is mutual, the iron attracting the magnet as much as it is attracted by it; so that if they were placed on pieces of cork or wood and made to swim on water, the iron would be found to advance towards the magnet as well as the magnet towards the iron; and if the iron were kept steady, the magnet would move towards it. A smaller degree of attraction than that which is observed by means of water may be discovered by placing the given body to swim upon quicksilver, and by presenting the magnet to it; in which case it will move with surprising velocity. In this method the following particulars must be minded, *viz.* the aperture of the vessel, in which the quicksilver is kept, must be at least six inches in diameter; otherwise, as the surface of the quicksilver descends near the sides of the vessel, and that curvature is proportionably greater in narrow vessels than in larger ones, the floating body, when the quicksilver is kept in a vessel of three or four inches, will be perpetually running towards the sides. The quicksilver must be very pure; but, as it is very difficult to find it, or to preserve it pure, it must be frequently passed through a funnel of paper, *viz.* a piece of writing paper rolled up conically, and having a small aperture of about a fortieth of an inch in diam-

M A G N E T.

ter; for, if the quicksilver be impure, the floating body will move with less facility upon it than upon water. The air about it must not be disturbed much, in order to keep the body without motion; in which state one of the poles of a strong magnet is to be presented on one side of it, in the same manner as when the experiment is tried on water, following the same precautions. The force of magnetic attraction varies according to the strength of the magnet, the weight and shape of the body presented to it, the magnetic or unmagnetic virtue of that body, the distance between it and the magnet, and some other circumstances. A piece of soft and clean iron is more powerfully attracted by a magnet than any other ferruginous body of similar shape and weight. The iron ores are attracted more or less forcibly, as they contain a greater or less quantity of metallic particles, as that quantity is in a more or less perfect metallic state, and as it is of a softer or harder nature; but all these, as well as hard iron and steel, are less forcibly attracted than soft iron. By presenting a piece of iron successively to the different parts of the surface of a magnet, the attraction will be found strongest at the poles of the magnet, or those points that are directed, when the magnet is freely suspended, towards the north and south; it will be found to decrease as the part towards which the iron is presented recedes from the poles, and it will be very little, or not at all, perceptible about those parts of the surface which are equidistant from the poles. The attraction, as we have already observed, is most powerful near the surface of the magnet, and is diminished in receding from it, so that if a piece of iron be placed in contact with one of the poles of a magnet, it will require a certain degree of force to separate them; at the distance of an inch from the pole, the attractive power, though much diminished, will be perceptible; and at a greater distance, it will be still weaker. However, the law of this diminution has not been satisfactorily ascertained; so that it is not known, whether it is twice, thrice, or any other number of times greater than at double that distance. In some cases, the attraction has seemed to decrease in the inverse ratio of the distances; but in others it has decreased much faster, or in different proportions at different distances; and the only general conclusion that has been deduced from a variety of experiments is, that the decrease of magnetic attraction is not slower than the inverse ratio of the distances, so that at double the distance it is half as strong, &c. In some other experiments with magnetic needles, the attraction appeared to decrease in the ratio of the cubes of the distances. Mr. Whiston states, that the absolute attractive power of different armed load-stones is, *ceteris paribus*, according to the quantity, not of their diameters or solidities, but of their surfaces, or in a duplicate proportion of their diameters. Whereas, the power of good magnets unarmed, not sensibly different in strength, similar in figure and position, but unequal in magnitude, is sometimes a little greater, sometimes a little less, than in the proportion of their similar diameters. He says, that the load-stone attracts needles that have been touched, and others that have not been touched, with equal force at unequal distances; *viz.* where the distances are to one another as five to two. According to his account, the attractive power of load-stones, in their similar position to, but different distances from, magnetic needles, is in the sesquiduplicate proportion of the distances of their surfaces from their needles reciprocally; or as the mean proportionals between the squares and the cubes of those distances reciprocally; or as the square roots or the fifth powers of those distances reciprocally. Thus the magnetic power of attraction, at twice the distance from the surface of the load-stone, is between a fifth and sixth

part of that power at the first distance; at thrice the distance, the power is between the fifteenth and sixteenth parts at four times the distance, the power is thirty-two times as small; and at six times the distance, eighty-eight times as small. Where it is to be noted, that the distances are not taken, as in the laws of gravity, from the centre; but from the surface: all experience assuring us, that the magnetic power resides chiefly, if not wholly, in the surfaces of the load-stones and iron; without any particular relation to any centre at all. The proportion here laid down was determined by Mr. Whiston, from a great number of experiments of Mr. Hauksbee, Dr. Brook Taylor, and himself. The force they measured by the chords of those arcs, by which the magnet, at several distances, draws the needle out of its natural direction, to which chords (as he has demonstrated) it is ever proportional. The numbers in some of their most accurate trials he gives us in the following table; setting down half the chords, or the sines of half those arcs of declination, as the true measures of the power of magnetism.

Distance in Inches.	Degrees of Inclination.	Sines of half Arcs.	Rat. sesquidupl.
20	2	175	466
14 $\frac{1}{2}$	4	349	216
13 $\frac{3}{4}$	6	523	170
12 $\frac{3}{4}$	8	697	138
11 $\frac{1}{4}$	10	871	105
10 $\frac{1}{4}$	12	1045	87
9 $\frac{1}{4}$	14	1219	70

Sir Isaac Newton supposes magnetic attraction to decrease nearly in the triplicate ratio of the distance. Mr. Martin observes, that the power of his load-stone decreases in the sesquiduplicate ratio of the distances inversely. Dr. Hellsam found it to be as the squares of the distances inversely, which ratio agrees with that of the ingenious Mr. Michell; others, as Dr. Brook Taylor and Mr. Muschenbroeck, are of opinion, that this power follows no certain ratio at all, but that it is much quicker at greater distances than at small ones, and that it is different in different stones. Muschenbroeck has made the following experiments in relation to this subject, and as they were accurately made, we shall here annex them. *Introd. Nat. Phil. c. 19.*

Exp. 1.—A cylindrical magnet, two inches long, and weighing 16 drams, was suspended to one scale of an accurate balance, and under it there was placed, upon a table, a cylinder of iron, which was exactly of the same bulk and shape. Things being thus prepared, the cylinder of iron was successively placed at different distances from the magnet, and at each distance the degree of attraction between the iron and the magnet was ascertained by weights put in the opposite scale of the balance. The results were as follows, *viz.*

Distance in Inches.	Attractions in Grains.
6	3
5	3 $\frac{1}{2}$
4	4 $\frac{1}{2}$
3	6
2	9
1	18
0	57

Exp. 2.—A spherical magnet, of the same diameter as the cylindrical one used before, but of greater strength, was affixed to one of the scales of the balance; and the cylindrical magnet, used in the preceding experiment, was placed upon the table, with its south pole upwards, and facing the north

M A G N E T.

north pole of the spherical magnet. In this disposition of the apparatus, the attractions were found to be as follow :

Distance in Inches.	Attractions in Grains.
6	21
5	27
4	34
3	44
2	64
1	100
0	260

Exp. 3.—Instead of the cylindrical magnet, the cylinder of iron was placed upon the table, and under the globular magnet. The result was as follows :

Distance in Inches.	Attractions in Grains.
6	7
5	9½
4	15
3	25
2	45
1	92
0	340

Exp. 4.—Instead of the iron cylinder, a globe of iron of the same diameter as the spherical magnet was placed upon the table, and the attractions were found to be as follow :

From the second and third experiments it appears, that, when in contact, a magnet attracts another magnet with less force than a piece of iron. This has been confirmed by many other experiments. But the attraction between two magnets begins from a greater distance than between the magnet and iron; hence it must follow a different law of decrement.

The attraction between a given magnet and a piece of iron, is subject to a variation arising from the weight and shape of the iron; there being a limit, in the weight and shape of the iron, in which the magnet will attract it more forcibly than either a greater or a smaller one: but this most advantageous weight and extension of the piece of iron can only be determined by actual experiment, it being various according to the various nature, strength, and shape of the magnet, as well as of the iron.

Magnetic attraction takes place between the magnet and such ferruginous bodies as were not magnetic before, or between the contrary poles of two magnets: but when two magnets are placed with their poles of the same name toward each other, then, instead of attracting, they repel each other. However, it often happens, that though the north pole of one magnet be placed near the north pole of another magnet, or the south pole of the one be placed near the south pole of the other, yet they attract each other: and sometimes they shew no attraction nor repulsion.

In order to reconcile this apparent contradiction, it is necessary to mention first another phenomenon, which takes place whenever a piece of ferruginous substance is brought near a magnet; and which indeed is the foundation of, and

serves to explain a great many, other appearances, otherwise unintelligible, in the science of magnetism.

The phenomenon, in short, is this: when a piece of iron, or any other substance that contains iron, is brought within a certain distance of a magnet, it becomes itself a magnet, having the poles, the attractive power, and in short every property of a real magnet. That part of it which is nearest to the magnet acquires a contrary polarity: thus, if an oblong piece of iron, A B, be brought within a proper distance of a magnet, so that the extremity, A, of the iron may be opposite the north pole of the magnet, then this same extremity, A, will become a south pole, and the other extremity, B, will become a north pole.

The magnetism acquired by being placed within the influence or the sphere of activity of a magnet, in soft iron lasts only whilst the iron continues in that situation, and when removed from the vicinity of the magnet, its magnetism vanishes immediately; but with hard iron, and especially with steel, the case is quite different; for the harder the iron or the steel is, the more permanent is the magnetism which it acquires from the influence of a magnet; but it will be in the same proportion difficult to render it magnetic. If, for instance, a soft piece of iron and a piece of hard steel, both of the same shape and size, be brought within the influence of a magnet at the same distance, it will be found that the iron will appear much more magnetic than the steel; but if the magnet be removed, the soft iron will instantly lose its magnetism, whereas the hard steel will preserve it for a long time.

From these observations two consequences are evidently deduced, *viz.* first, that there is no magnetic attraction but between the contrary poles of two magnets; for the iron, or other ferruginous body, that is presented to the magnet, must become itself a magnet before it be attracted: and secondly, it appears why a magnet must attract a piece of soft iron more forcibly than hard iron, and much more than hard steel, *viz.* because the hard iron, and more especially the hard steel, does not become so strongly magnetical as soft iron, when presented to a magnet.

We may now resume the subject of magnetic repulsion, and shew why the magnetic poles of the same name may repel, attract, or not act at all, upon one another.

Indeed, the law of repulsion being always exerted between magnetic poles of the same name, nearly as strong as the attraction between those of different name, remains certain and immutable; but it often happens, that one of the magnets, being more powerful than the other, will change the pole of that other magnet, in the same manner as it gives magnetism to any other piece of iron which is exposed to its influence, and then an attraction will take place apparently between magnetic poles of the same names; though in fact it is an attraction between poles of different names, because one of them has been actually changed. Thus, suppose that a powerful magnet be placed with its north pole very near the north pole of a weak magnet; it will be found, that instead of repelling, they will attract each other, because that part of the weak magnet, which before was a north pole, has been changed into a south pole by the action of the strong magnet.

As those bodies which are possessed of any magnetism cannot be very readily affected by the influence of another magnet, for the very same cause which renders them capable of retaining any magnetism at all, namely, the hardness; and, as the power of a magnet diminishes in proportion to the distances from its surface, it follows, that when the north or south pole of a weak magnet is from a considerable distance, gradually brought near the like pole of a powerful magnet,

M A G N E T.

magnet, the pole of the weak magnet cannot be changed very easily; hence, beyond a certain distance, *viz.* before the said pole be changed, the two magnets must exert a repulsion against each other; but when the small magnet has been brought so near the powerful one, as that its pole may begin to be changed, then neither an attraction nor a repulsion will take place; and when the two magnets are approached nearer than that limit, then, the pole of the weak one being changed, an attraction will ensue.

After these observations, the ingenious reader may easily imagine that the decrease of repulsion between homogeneous magnetic poles must be at least as much, if not more irregular than the decrease of the attraction at different distances. It is likewise evident, that many objects must be had in view, in attempting to investigate the law of that decrease.

5. If a magnet be cut through the axis, the parts or segments of the stone, which before were joined, will now avoid and fly each other. 6. If the magnet be cut by a section perpendicular to its axis, the two points which before were conjoined, will become contrary poles; one in one, the other in the other segment. 7. Iron is not only attracted by a magnet, even more than another magnet, and equally attracts it, but also receives virtue from the magnet by application to it, or barely from an approach near it, though it do not touch it; and the iron receives this virtue variously, according to the parts of the stone it is made to touch, or even but to approach to; the part of the iron or steel which is nearest to the magnet acquiring the contrary polarity, &c. In order to communicate the magnetic virtue more effectually, the following methods are made use of: *viz.* it has been discovered, that iron rubbed upon one of the poles of the magnet acquires much greater virtue than from any other part of it; and this is more considerable from an armed magnet than from a naked one. Farther, the more gently the iron is pressed, and the more it is pressed against the pole, the more magnetical it becomes. Again, it is more convenient to impregnate iron on one pole, than on both sides successively; because the iron receives magnetic virtue from each pole, in contrary directions, which destroy each other's effects. Moreover, the iron is much better impregnated by pressing it uniformly and in the same direction, according to its length, than by rubbing it by the middle; and the extremity which touches the pole last, retains the greatest virtue: it is also of importance, that the length of the iron be considerable. Besides, a piece of polished steel, or of pointed iron, receives more virtue than mere iron, or iron of the same figure: and, *ceteris paribus*, a piece of iron that is long, small, and pointed, is more strongly impregnated than that of any other form. 8. If an oblong piece of iron be any way applied to the stone, it receives virtue from it, only as to its length. 9. The magnet loses none of its own virtue by communicating any to the iron, but has it rather improved; though this is doubted by Mr. Savery; and this virtue it can communicate to the iron very speedily; though the longer the iron touches or joins the stone, the longer will its communicated virtue remain in it; and a better magnet will communicate more of it, and sooner, than one not so good.

It is obvious that when the iron, steel, or any ferruginous body is applied in contact with the magnet, it acquires a stronger power than if it be placed at some distance from its surface. A magnet can never communicate a greater power than itself possesses, or even an equal degree of it; but several magnets, of nearly an equal degree of magnetism, when joined together, have a stronger power than one of them singly: hence, in order to impart a strong magnetic power to a given body A, by means of a weak magnet B,

we must first render several bodies, C, D, E, F, &c. weakly magnetic; and then, by properly joining C, D, E, F, &c. together, we may communicate to another body, or several other bodies, a stronger magnetism, till, at last, we shall be able to communicate to A the required degree of magnetic power.

The late Dr. Gowin Knight practised a method, which he never published, of communicating to iron a very considerable magnetic virtue, and also of increasing that of feeble magnets. From a report delivered to the Royal Society in 1744, it appears that he had prepared a small eight-cornered bar of steel, three inches and almost $\frac{7}{10}$ this long, and about half an ounce troy in weight, which lifted by one of its ends about eleven of the same ounces; that another plain bar of steel, of a paralleloiped form, $5\frac{5}{10}$ inches long, $\frac{4}{10}$ ths of an inch broad, and $\frac{2}{10}$ ths of an inch thick, weighing 2 ounces $8\frac{1}{2}$ penny-weights, lifted, in like manner, by one of its ends, twenty troy ounces; that a steel bar, almost of the same form as the last, but only four inches in length, capped or armed with iron at each end, cramped with silver, and weighing all together one ounce fourteen penny-weights, lifted by the feet of the armour full four pounds troy; and that a single block of steel, of a paralleloiped form, almost four inches long, $1\frac{7}{8}$ high, and $\frac{3}{8}$ ths of an inch thick, armed with iron, cramped with brass, and suspended by a ring of the same, and weighing all together fourteen ounces one penny-weight, lifted by the feet of the armour 14 pounds $2\frac{1}{2}$ ounces troy weight. He also exhibited a compound artificial magnet, consisting of twelve bars of steel armed, which lifted by the feet of the armour, as the last, 23 troy pounds $2\frac{1}{2}$ ounces. At the same time he presented before the Society a small armed load-stone, which, with its armour, weighed seven penny-weights fourteen grains, and which could scarcely lift two ounces; but improved by his method, it sustained six ounces eighteen penny-weights and three grains. See *Armed MAGNET*, and *Artificial MAGNET*.

10. Iron will receive magnetism more easily than steel; the soft steel receives it much more easily than the spring-tempered, and the spring-tempered much more easily than the hard: but a piece of spring-tempered steel will not retain near so much magnetism, and is therefore incapable of being excited to the same degree as hard steel; soft steel will retain it still less; and iron, which is the softest of all, and in which the acquired magnetism is the strongest, scarcely retains any, when it is removed from the influence of the magnet. Other ferruginous bodies preserve it for a longer or shorter time, according as they participate more of the nature of hard steel, or of that of soft iron. Mr. Michell has evinced the truth of these observations both by reasoning and experiment. There are other bodies, besides iron and steel, which are susceptible of magnetism; these are probably no other than iron in some shape or other, or bodies that have a mixture of them: such are all sorts of iron ore after ignition, and some before. It is observable, that several of the hard ores of iron, which are not affected in the least by the magnet in their natural state, are vigorously attracted by it when moderately roasted; that the calces of iron, by slight roasting with inflammable additions, are made to obey the load-stone, and revived into their metallic form, each particle appearing now to be perfect iron; whilst the calces of other metals are in no degree revived, without being brought into fusion.

The ores of iron are attracted more or less readily, according as they contain a greater or a smaller quantity of metal, and as that metal is in a more or less perfect metallic state. By the action of fire, iron ores are generally put into

a state

M A G N E T.

a state of being much more readily attracted. The scales which are separated from the surface of red-hot iron when hammered, and the particles of burnt steel that are produced from the collision of a flint and steel, are attracted by the magnet nearly as well as pieces of good iron that equal them in bulk. The black calx of iron is attracted very weakly. The red calx, or rust, whether it be produced by the action of acids, of fire, or by exposure to the atmosphere, is attracted very little; but it never becomes quite insensible of the magnet's action, though it be repeatedly washed and purified. It is observable, that a quantity of iron is attracted with the least force, when reduced into the smallest bits, or finest powder. The ores of other metals are generally, though weakly, attracted by the magnet, thus indicating that they contain some iron: such are the ores of lead, of tin, and of copper. Native cinnabar is likewise attracted; but the factitious cinnabar is not. The pure metals are not attracted. Of the pure metals, zinc, bismuth, and particularly cobalt, as well as their ores, are almost always attracted by the magnet. Antimony, unless it be first exposed to a gentle fire, is not attracted. Arsenia is not attracted at all. A certain sort of bismuth possesses a singular property of being repelled on every side by the magnet. The other minerals, besides the metallic, are almost all attracted by the magnet, at least after having been exposed to the action of fire. Of the pure earths, the calcareous is least, or not at all, and the siliceous the most frequently, attracted.

There are also several sorts of heavy, shining, opaque, black, or dark chocolate-coloured sand, most of which, if not all, are iron ores, which are susceptible of magnetism. Of this kind is the dark-brown sand in emery: we may also refer to this class most brads, and several other metals; and bricks that have been much burnt in the fire. The magnetism of these is probably owing to a small quantity of iron mixed with them. What is in the brads, Mr. Michell conjectures, may come from the lapis calaminaris, which is said to have often a small mixture of iron in it; but Mr. Arderon, who has succeeded in giving magnetism and polarity to brads, has doubts as to the mixture of iron with brads: particularly, because brads fluxes with a much less degree of heat than iron, and iron naturally swims in fluid brads. Phil. Trans. vol. 1. p. 774.

Mr. Cavallo made several experiments, with a view of ascertaining the magnetism of brads, and investigating the cause of it. The result is as follows: It appears, he says, "1st. That most brads become magnetic by hammering, and lose the magnetism by annealing or softening in the fire, or at least its magnetism is so far weakened by it, as afterwards to be only discoverable when set afloat on quicksilver.

"2dly. That the acquired magnetism is not owing to particles of iron or steel imparted to the brads by the tools employed, or naturally mixed with the brads.

"3dly. Those pieces of brads which have that property, retain it without any diminution after a great number of repeated trials, viz. after having been repeatedly hardened and softened. But I have not found any means of giving that property to such brads as had it not naturally.

"4thly. A large piece of brads has generally a magnetic power somewhat stronger than a smaller piece; and the flat surface of the piece draws the needle more forcibly than the edge or corner of it.

"5thly. If only one end of a large piece of brads be hammered, then that end alone will disturb the magnetic needle, and not the rest.

"6thly. The magnetic power which brads acquire by hammering has a certain limit, beyond which it cannot be

increased by farther hammering. This limit is various in pieces of brads of different thicknesses, and likewise of different quality.

"7thly. Though there are some pieces of brads which have not the property of being rendered magnetic by hammering, yet all the pieces of magnetic brads, that I have tried, lose their magnetism, so as no longer to affect the needle, by being made red-hot; excepting indeed when some pieces of iron are concealed in them, which sometimes occurs: but in this case, the piece of brads, after having been made red-hot and cooled, will attract the needle more forcibly with one part of its surface than with the rest of it; and hence, by turning the piece of brads about, and presenting every part of it successively to the suspended magnetic needle, one may easily discover in what part of it the iron is lodged.

"8thly. In the course of my experiments on the magnetism of brads, I have twice observed the following remarkable circumstance:—A piece of brads, which had the property of becoming magnetic by hammering, and of losing the magnetism by softening, having been left in the fire till it was partially melted, I found, upon trial, that it had lost the property of becoming magnetic by hammering; but having been afterwards fairly fused in a crucible, it thereby acquired the property it had originally, viz. that of becoming magnetic by hammering.

"9thly. I have likewise often observed, that a long continuance in a fire so strong as to be little short of melting-hot, generally diminishes, and sometimes quite destroys, the property of becoming magnetic in brads. At the same time, the texture of the metal is considerably altered, becoming what some workmen call *rotten*. From this it appears, that the property of becoming magnetic in brads by hammering, is rather owing to some particular configuration of its parts, than to the admixture of any iron; which is confirmed still farther by observing, that Dutch plate brads, which is made not by melting the copper, but by keeping it in a strong degree of heat whilst surrounded by lapis calaminaris, also possesses that property; at least, all the pieces of it, which I have tried, have that property.

"From these observations it follows, that when brads is to be used for the construction of instruments wherein a magnetic needle is concerned, as dipping needles, variation compasses, &c. the brads should be either left quite soft, or it should be chosen of such a sort as will not be made magnetic by hammering; which sort, however, does not occur very frequently."

For the remarks of Mr. Bennett on Cavallo's experiments, and the reply of the latter, we refer to the Phil. Trans. for 1792, and the appendix to Cavallo's Magnetism. This author examined other metallic substances, viz. copper, zinc, and platina. The two former manifested no signs of being magnetic: and of various pieces of platina, some did not acquire any magnetism by hammering, and others were rendered evidently attractable by the magnet by three or four strokes, and about ten strokes gave them the full power of which they were susceptible. But when the grains of platina that were made capable of being attracted by the magnet under the operation of hammering were put upon a charcoal fire, and made red-hot by means of a blowpipe, and were afterwards presented first to the magnet and also to the suspended needle, they shewed not the least sign of attraction. Heat, therefore, deprives them, as well as brads, of the property acquired by hammering. Mr. Cavallo concludes upon the whole from experiments of this kind, that the power of being attracted by the magnet may exist, or may belong to other substances, independent of iron; and therefore that the attraction of

MAGNET.

a few particles of any unknown substance by the magnet is not a sure sign of the presence of iron. Although it be true, that iron is always attractable by the magnet, yet it does not hence follow, that whatever is attracted by the magnet must be iron.

Amber, and other combustible minerals, are generally attracted by the magnet, especially after burning. Of the precious stones, those that are pellucid, as the diamonds and crystals, are not attracted. The amethyst, topaz, chalcodony, and generally those which are deprived of their colour by fire, are not attracted. The other precious stones are all attracted, *viz.* the ruby, especially the oriental, the chrysolite, and the tourmalins. The emerald, and particularly the garnet, are not only attracted, but frequently acquire an evident polarity from the influence of a strong magnet, so that afterwards they are attracted from one side and repelled from the other. The opal is but weakly attracted. Almost every part of animal or vegetable bodies, after combustion, is in great measure attracted by the magnet. The flesh, and especially the blood, after burning, are attracted most, but the bones are attracted less powerfully. The vegetables, after burning, are almost all, though not with equal force, attracted by the magnet. But unburned and moist animal or vegetable substances very seldom, if ever, shew any perceptible attraction towards the magnet. Even soot, and the dust which usually falls upon whatever is left exposed to the atmosphere, are sensibly attracted by the magnet. Hence it appears that iron, though divided into exceedingly small particles, is in some state or other mixed with every substance; that it is to be found in animals, in vegetables, in minerals, and even in the air; that in every state of existence it always shews some attraction towards the magnet; and that its existence in several substances can be discovered by no other known method besides the magnet. But we have already observed, that there is reason for presuming, that some bodies independent of iron, are attracted by the magnet.

11. A needle touched by a magnet will turn its ends the same way towards the poles of the world, as the magnet itself does. 12. Neither the load-stone nor needles touched by it do conform their poles exactly to those of the world, but have usually some variation from them; and this variation is different in divers places, and at divers times in the same place. (See DECLINATION, DIPPING, and VARIATION.) 13. A load-stone will take up much more iron when armed or capped, than it can when naked. See ARMS and ARMED MAGNET.

It has also been observed, that amongst the natural magnets, the smallest generally possess a greater attractive power, in proportion to their size, than those which are larger. There have been often seen natural magnets not exceeding the weight of 20 or 30 grains, which could lift a piece of iron that weighed 40 or 50 times more than themselves. Mention is made of a small magnet wore in a ring, which weighed about three grains, and was capable of taking up 746 grains, or nearly 250 times its own weight; and we have seen one which could not weigh more than six or seven grains, and was capable of lifting a weight of about 300 grains. But magnets of above two pounds weight seldom lift up ten times their own weight of iron.

It often happens, that a natural magnet, cut off from a larger load-stone, will itself be capable of lifting a greater weight of iron than the original large load-stone from which it was cut off. This must be imputed to the heterogeneous nature of the large load-stone; for, suppose that one part of it contains a good quantity of pure metal strongly magnetical, the rest of it being impure or mixed with other substances,

it is plain that the impure part can only obstruct the action of the purer part; hence this latter, being separated from the rest, must act more powerfully than the whole together did.

14. The force of a magnet may be variously increased or lessened by the various application of iron, or another magnet, to it. Thus, the holding of a piece of iron of some magnitude to one pole of a magnet, increases the attraction of the other pole, so as to enable it to lift a greater weight. Also, the attractive power of a magnet may be increased considerably by gradually adding more and more weight to it; for by this means it will be found that the magnet will keep suspended on one day a little more weight than it did the preceding day; which additional weight being added to it on the following day, or some time after, it will be found that the magnet can keep suspended a weight still greater, and so on as far as a certain limit.

On the contrary, by an improper situation, or by putting a very small weight of iron into it, the magnet may gradually lose much of its strength.

Heat weakens the power of a magnet; and a white heat destroys it entirely, or at least in a great measure. Hence it appears, that from this cause alone, besides others which may concur, the power of a magnet must be continually varying.

15. A strong magnet at the least distance from a lesser, or a weaker, cannot draw to it a piece of iron adhering actually to such lesser or weaker stone; but if it come to touch it, it can draw it from the other: but a weaker magnet, or even a little piece of iron, can draw away or separate a piece of iron contiguous to a greater or stronger load-stone.

16. In these northern parts of the world, as various authors have said, the north pole of a magnet generally has an attractive power somewhat stronger than the south pole; but in the southern parts of the earth, the south pole of the magnet is said to possess the greatest attractive power. However, this law has not yet been properly ascertained.

17. Neither the attraction nor the repulsion of magnetism is sensibly affected by the interposition of bodies of any sort, except iron or ferruginous bodies in general. Thus, suppose that when a magnet is placed at an inch distance from a piece of iron, there is required an ounce of force to remove it; or, which is the same thing, (suppose that the attraction towards each other is equal to one ounce; it will be found that the same degree of attraction remains constantly unaltered, *viz.* always equal to one ounce, though a plate of other metal, or of glass, or paper, or other body, be interposed between the magnet and the iron; or though they be inclosed in separate boxes of glass or other matter. Neither the absence or presence of air has any effect upon them. In short, no other substance besides iron, or those bodies which contain that metal in any of its metallic states, does sensibly affect the attraction or repulsion of magnetism. Accordingly, Mr. Boyle found this true in glasses sealed hermetically; and glass is a body as impervious, as most are, to any effluvia. The magnetic virtue is sensibly continued through the substance of several contiguous bodies or pieces of iron, as keys, &c. It pervades the pores of the hardest bodies; and equally attracts the iron in vacuo, as in open air.

18. It has frequently been observed, that bars, and other pieces of iron, by having remained a long time in one situation, have become magnetic. Sometimes iron bars, which were not capable of a permanent magnetism on account of their softness, have in time, and by being left exposed to the atmosphere in a due situation, acquired a considerable degree of magnetism; but it has been also remarked,

M A G N E T.

marked, that those bars have, at the same time, become harder; which is, perhaps, owing to a partial calcination, or to some other hitherto unascertained change in the nature of the iron.

The polarity thus communicated by the earth to iron bars, is more or less permanent, in proportion to the degree of hardness of the iron, the time of their remaining in one situation (the most proper being that of the dipping-needle), and lastly, the shape of the iron, or the proportion between the thickness and length of the pieces.

An oblong piece of iron made red-hot, and then left to cool in the magnetical line, acquires thereby a degree of magnetism, which is more or less permanent, according to the nature of the iron. The reason of which is, because, whilst red-hot, the iron is soft, and therefore the earth can render it magnetic more easily; but, when cooled, it becomes harder, and consequently more tenacious of the acquired power.

In drilling, filing, hammering, and, in short, in all those cases in which iron, steel, &c. is put into violent action, some of the pieces concerned frequently acquire a considerable degree of magnetism; the origin of which must be derived from the earth, and from the changeable nature of the metal, or the vicissitudes of heat, cold, and vibratory motion, in which it is accidentally put.

Professor Robison found, that when a good magnet was struck for $\frac{3}{4}$ ths of an hour, and allowed in the mean time to ring, its efficacy was destroyed; although the same operation had little effect when the ringing was impeded; so that the continued exertion of the cohesive and repulsive powers appears to favour the transmission of the magnetic as well as the electric fluid.

It seems that, for the same reasons, magnetism is in certain cases produced by means of electricity; the particulars observed concerning which are the following, and they were ascertained by means of the most powerful electrical machine that has been yet made. They in a great measure coincide with those made with other machines.

When the bar or needle is laid horizontally in the magnetic meridian, whichever way the shock of an electric jar or battery enters, the end of the bar that stands towards the north will acquire the north polarity, *viz.* the power of turning towards the north when freely suspended; the other end acquiring the south polarity. If the bar, before it receives the shock, has some polarity, and is placed with its poles contrary to the usual direction, then its original polarity is always diminished, and often reversed.

When the bar or needle is struck standing perpendicularly in these parts of the world, its lowest end becomes the north pole, even when the bar had some magnetism before, and receives the shock whilst standing with its south pole downwards. When all the other circumstances are alike, the bars seem to acquire an equal degree of magnetic power, whether they are struck whilst standing horizontally in the magnetic meridian, or perpendicular to the horizon.

When a bar or needle is placed in the magnetic equator, the shock sent through its length very seldom, if ever, renders it magnetic; but if the shock be passed through its width, then the needle becomes magnetic, the extremity of it which was laid towards the west, generally becoming the north pole.

If a needle or bar strongly magnetic, or a natural magnet, be struck by the electric shock, its power is thereby diminished.

When the shock is too strong, with respect to the size of the steel needle, so as to render it considerably hot, then it

acquires either none at all, or a very small degree of magnetism.

For these experiments, the bars or needles must be proportioned to the degree of electric power; otherwise they will not succeed. See Van Marum's account of a very powerful electrical machine, constructed for the Museum of Teyler at Haerlem; and Cavallo's Treatise on Electricity, vol. i. p. 66, and vol. ii. p. 282.

Hence, a stroke of lightning, which is an electrical phenomenon, often renders magnetic pieces of iron, or steel, or those bodies which contain iron, as certain bricks, &c.

If one pole of a magnet, for instance the north, be applied to one end, C, of an oblong piece of iron or steel, like C D, (*fig. 4.*) that end, C, will become a south pole; and if the bar, C D, be very long, there will be found a part of it, not far distant from C, which is possessed of the north polarity; and this is followed by another part possessed of the south polarity; and so on alternately, till the power becomes imperceptible; the number of those successive poles depending upon the strength, and principally upon the length of the bar; but if the bar be of a proper length and thickness, which must be likewise proportioned to the strength of the magnet employed, then the bar will have only two poles, its other extremity, D, acquiring the north polarity.

In the latter case, if the pole of the magnet be gradually moved along the surface of the bar from C as far as D, it will afterwards be found, that the polarity of the bar is entirely changed, the extremity, C, being now possessed of the north, and the extremity, D, of the south polarity.

It is evident, that, whilst the magnet is advancing along the surface of the bar, the south polarity of the end C, before it changes into a north polarity, must decrease in strength; and that when the magnet is at a certain point M, the end, C, has no polarity at all; its south polarity being just vanished, and the north polarity just beginning. With respect to the extremity D, it must be observed, that its north polarity, by the approach of the magnet, is increased as far as a certain limit H; after which, as the magnet comes still nearer to D, the north polarity of this extremity decreases, till it vanishes when the magnet is arrived at a certain point N; after which its north polarity begins to be changed into a south one.

The points, M and N, have been called the *points of indifference*; because, when the magnet is at M, the extremity, C, of the bar has neither the south nor the north polarity; and when the magnet is at N, the end, D, has no polarity. The point, H, has been called the *culminating point*, because, when the magnet is at that point, the polarity first acquired by the end, D, of the bar is the strongest.

As the determination of these points, in bars of different sorts of iron, of different lengths, &c. not only shews more evidently the action of the magnet, and points out the advantages and disadvantages attending the practical methods of making artificial magnets, but is besides likely to open the way to farther discoveries; there have been no pains spared to investigate the particulars on which their situation depends, and a vast number of accurate experiments have been made for that purpose; but, notwithstanding those endeavours, such is the various nature of magnets, of iron, &c. that the present knowledge of the subject does not allow these points to be determined in a given bar, without actual experiments. The general laws which may be deduced from the various experiments made for this purpose, are the following:

1. The points M, H, and N, do not come always in the order shewn by the figure; but though their order is not always the same, yet it is evident that the point, H, can

M A G N E T.

never coincide with, or come after N, viz. nearer to the end D, than the point N.

2. When the bars differ in length only, every thing else being the same, the longer the bar is, (as far as a certain limit, which depends on the strength of the magnet employed,) the greater is the distance C M.

3. The stronger the magnet is which is employed, the greater is the distance C M, as far as a certain limit, which depends upon the proportion between the power of the magnet and the length of the bar; and beyond which limit C M will be shorter than if a weaker magnet had been used.

4. When the bars differ in length only, every thing else being the same, the distance, C H, is greater in a longer than in a shorter bar, as far as a certain limit, which depends as has been mentioned above.

5. The stronger the magnet is which is used, the greater is the distance C H, as far as a certain limit, which depends as above.

6. In a longer bar, every thing else being the same, the distance, C N, is greater than in a shorter one, as far as a certain limit, &c.

7. The distance C N, in bars of equal length, is greater when a stronger than when a weaker magnet is used, as far as a certain limit, &c.

8. When the bars differ only in thickness, every thing else being the same, the distance, C M, is greater in thicker than in thinner bars; but the distance, C N, is nearly the same in them all, as far as a limit, which depends as before-mentioned.

9. Lastly, when the bars differ only in hardness, the distances C M, C H, C N, are sometimes equal, sometimes greater, and sometimes shorter, in the harder than in the softer bars.

Besides the points of indifference and culmination, there is another point to be considered, namely, the magnetic centre, which is the point or part between the two poles, where the magnet has no attraction nor repulsion. With respect to this point, we shall briefly observe, that it does not always lie midway between the two poles; and that, when one pole of a magnet is drawn over the surface of an oblong piece of iron, as in the before-mentioned experiment, the magnetic centre moves forwards in proportion as the magnet is advanced; but at a certain limit, both the magnet and the said centre are in the same place, or rather in opposite sides of the thickness of the bar. The motion and place of the magnetic centre are subject to a great deal of variety, arising from the nature, length, and thickness of the bar, as well as from the strength of the magnet, and from the manner of drawing it along the surface of the iron or other ferruginous body.

When any magnet, but especially an oblong one, having two poles, is broke in two, the magnetic centre of each part is at first generally much nearer that end of the piece which is contiguous to the fracture; but in time it advances nearer the centre of the piece.

What has been observed concerning oblong pieces of iron or steel, may serve to explain the phenomena which take place in pieces of an irregular form; the particular enumeration of all which cases would be endless, and of little, if at all of any use.

Every piece of iron or ferruginous body is capable of retaining only a certain degree of magnetic power; so that if a strong magnet be applied to a comparatively small piece of steel, that piece, whilst it remains within the influence of the magnet, will appear to be very powerfully magnetic;

but, as soon as it is removed from the vicinity of the magnet, its power begins to decrease, and in a short time comes down to that degree which the piece of steel is capable of, and which may be called *its point of saturation*. Hence it follows, that if a certain magnet is just sufficient to communicate to a piece of iron or steel the full power of magnetism, of which that piece is capable, a stronger magnet will not increase it in the least.

19. The power or virtue of a magnet, and of iron or steel impregnated with the magnetic virtue, may be impaired by long lying in a wrong position, with regard to the earth or with respect to each other. Thus, if two magnets be placed so, that their contrary poles may be contiguous to each other, they will preserve one another's power; but if the north pole of one be placed near the north pole of the other, and the south near the south, then they will entirely destroy or diminish each other's magnetism; and if their original powers were very unequal, the polarity of the weaker magnet will be changed by the action of the stronger one.

In general, the same means which facilitate the communication of magnetism, when pieces of iron, &c. are properly situated with respect to the poles of the earth, or of other magnets, will likewise facilitate the loss of magnetism, when the magnets are improperly situated; thus, a red heat destroys in a great measure, or entirely, the power of a magnet. A steel bar, strongly magnetic, will have its power much diminished by being repeatedly struck between two stones, especially if it be struck standing in a direction perpendicular to the magnetic meridian. A bar of pretty hard iron, which has acquired some degree of permanent magnetism, by being made red-hot, and then cooled in the direction of the magnetic line, will have that power destroyed, or much diminished, by a few smart blows on its middle.

20. Some have said that iron or steel has been rendered heavier or lighter by being magnetic; but Gassendus, Merfennus, and Gilbert maintain the contrary; and it seems to be allowed, upon the whole, that its weight is not thus affected. Mr. Whiston says that he found, by accurate experiments with large needles, that after the touch they weighed less than before. One of 4584½ grains lost 2½ grains by the touch; and another of 65,726 grains lost no less than 14 grains. Cavallo suggests, that the vicinity of iron, or of some other ferruginous body, might have had some action on the magnetic steel when it was weighed.

21. A piece of iron wire, well touched, will, upon being bent round in a ring, or coiled round on a stick, &c. generally quite lose its directive virtue; but it will always have it much diminished: and yet if the whole length of the wire was not entirely bent, so that the ends of it, though but for the length of one-tenth of an inch, were left straight, the virtue will not be destroyed in those parts: though it will in all the rest. This was first observed by Messrs. Grimaldi and De la Hire; and is confirmed by the experiments of Dr. Derham; who adds farther, that though coiling or bending the wire as above would always destroy its virtue by day, yet it would not do it in the evening. In order to weaken or destroy the magnetism of a wire by bending, let the magnetic power be communicated to an iron or soft steel wire, of about four or five inches in length, and about ⅓rd of an inch in diameter; then roll it round a small stick, so as to make four or five revolutions round the stick; after which, on straightening the wire again, its magnetism will be generally found to be quite destroyed by the bending, or considerably weakened.

The effect is the same with shorter or longer wires; for

M A G N E T.

if they make one revolution round the stick, the effect will take place; which is evidently owing to the stress or derangement of the particles of the wire, as is rendered more evident by the following observation; *viz.* that if the wire be of such springy nature, as to recover its straight situation, if left to itself, after coiling it round the stick, then its magnetism is either not at all, or little diminished: so that, in order to produce the above-mentioned effect, a straining of the parts of the wire is absolutely necessary.

When only the middle of the wire is bent, and its extremities remain straight, then the magnetism is seldom destroyed, or even diminished.

If a piece of magnetic wire be cleft or split lengthwise, the parts will have sometimes contrary, and sometimes the same poles as they had when in one piece. When one part is much thinner than the other, then this slender part will generally have its poles reversed.

22. The sphere of the activity of magnets is greater and less at different times: in particular that preserved in the repository of the Royal Society will keep a key or other body suspended to another, sometimes at the height of eight or ten feet; and at others, not above four feet. (See 4 above.) To which we may add, that the variation of the magnetical needle from the meridian varies at various times of the day; as appears from some experiments of Mr. Graham. See DECLINATION and VARIATION.

23. The directive power of a magnet is extended to a greater distance than its attractive power; for instance, if a magnet be freely suspended, another magnet properly situated within a certain distance of the former, will turn it out of its wonted direction; yet the degree of attraction exerted by these magnets against each other, is not sensible at that distance; which may be easily tried, by fixing one of the magnets to the scale of a balance. The reason of this property is, that the directive power depends both upon the attraction of the poles of different names, and on the repulsion of those of the same name; whereas, the attraction takes place only between poles of different names. In order to render this explanation more intelligible, imagine that a magnetic needle is freely suspended, and is placed within the influence, or sphere of action of a magnet. In this disposition, suppose that the north pole of a magnet attracts the south pole of a magnetic needle with a force equal to ten grains; and, as the attraction between poles of different names is nearly equal to the repulsion between poles of the same name, it follows, that the same north pole of the magnet repels the north pole of the magnetic needle with a force equal to ten grains: but these two forces both concur in altering the direction of the needle; therefore, the endeavour of the magnet to turn the needle's direction is equal to 20 grains; whereas the attraction, or the force by which the needle is drawn towards the magnet, is only equal to the difference between the two above-mentioned opposite forces, which difference arises from the pole of the magnet being nearer to one than to the other of the poles of the needle. The same reasoning may be applied to the action between the south pole of the magnet and the suspended needle.

24. By twisting a piece of wire touched with a magnet, its virtue is exceedingly diminished, and sometimes so disordered and confused, that in some parts it will attract, and in others repel; and even in some places, one side of the wire seems to be attracted, and the other side repelled by one and the same pole of the stone. The effect of magnets on a crooked wire may be shewn in the following manner. Let an iron wire of about a quarter of an inch in diameter, and four or five inches long, be bent somewhat like a Gothic arch, *viz.* with a sharp corner in the middle, A B C, *fig.* 5,

and tie it fast to a cross bar, or let an assistant hold it with the corner downwards; then apply either pole of the magnet, D E, to one of its extremities A, and whilst the magnet remains in that situation, apply a piece of iron, H, of no great size, to the corner C, and you will find that the iron remains suspended. Now, if another magnet be applied to the other extremity, B, of the crooked wire, so that the pole, G, may be contrary to the pole E, the iron, H, will immediately fall off; but if the pole, G, be analogous to the pole E, *viz.* be both south, or both north, then the iron, H, not only will remain adhering to C, but the said corner will be capable of supporting a weight still greater than H. The reason of which is, that in the former case, the extremities, A, B, of the bent wire being possessed of different polarities, the corner, C, was the magnetic centre, where there is no attraction nor repulsion; whereas, in the second case, both extremities of the bent wire being possessed of the same polarity, the corner, C, was necessitated to acquire the contrary polarity; and in this case, the bent wire must have two magnetic centres, *viz.* one on each side.

25. A piece of wire that has been touched, being split or cleft lengthwise, in two, the poles are sometimes changed; as in a cleft magnet; the north becoming the south, and the south the north: and yet sometimes one-half of the wire will retain its former poles, and the other half will have them changed. When one part is much thinner than the other, then the slender part will generally have its poles reversed. (See No. 21 *supra.*) To which it may be added, that laying one or other side of the half uppermost, causes a great alteration in its tendency or aversion to the poles of the magnet.

26. A wire being touched from end to end with the same pole of the magnet, the end at which you begin will always turn contrary to the pole which touched it: if it be again touched the same way with the other pole of the magnet, it will then be turned the contrary way.

27. If a piece of wire be touched in the middle with only one pole of the magnet, without moving it backwards or forwards; in that place will be the pole of the wire, and the two ends will be the other pole.

28. If a magnet be heated red-hot, and again cooled either with its south pole towards the north in a horizontal position, or with its south pole downwards, in a perpendicular position, its poles will be changed.

29. Mr. Boyle (to whom we are indebted for the following magnetical phenomena) found he could presently change the poles of a small fragment of a load-stone, by applying them to the opposite vigorous ones of a large magnet. Dr. Knight discovered a method of changing the direction of the poles in natural magnets, multiplying and variously placing them at pleasure. In the first instance, recorded in the Philosophical Transactions, he inverted the poles of a magnet by a process which required only a minute's time; so that the same end, which before attracted the south end of the needle, now attracted the north and repelled the south, and *vice versa*: in the same time he again turned the direction of the polarity of the stone at right angles, to its former direction; and afterwards inverted this last direction of the poles. In the second series of experiments, he cut a piece of natural load-stone into the shape of a parallelepiped $\frac{8}{10}$ ths of an inch long, $\frac{7}{8}$ ths of an inch broad, and $\frac{1}{2}$ ths of an inch in thickness: its weight was three drams and ten grains. In this stone he placed the magnetical virtue in such a manner, that the two opposite ends became, both of them, south poles, and the middle was quite round a north pole. The two opposite ends of another stone were made both north poles, and the two opposite sides south poles. At one end of another stone he placed a north pole, surrounded by a south; and at the other end a south, surrounded by a north pole; so that the edges of each

M A G N E T.

each surface had a pole of a different denomination from that which occupied the middle. On another occasion, he inverted the poles at the ends of a piece of magnet, and then transferred them to the sides of the stone. All these changes of the poles are easily produced by steel bars, A B, C D, (*Plate VI. Magnetism, fig. 6.*) impregnated with a strong magnetic virtue, by which the piece of magnet, E F, placed between them is so affected, that the poles may be changed at pleasure, and excited in places that are touched by the ends of the bars. Mr. Michell has shewn the method of doing this both in small and large magnets. If a small and short magnet is to have its poles changed, lay the supporters described under *Armed MAGNETS* so, that the centre of their force shall, at each end, lie at the end of the line designed to be the axis of the magnet, and touch it double in the manner explained under *Artificial MAGNET*, as near as may be in that direction. If the poles are to be converted, and the magnet be long enough, touch it double, according to the directions for converting the poles of an artificial magnet; then support it, and touch it over again with fresh touches: or if the magnet is short, apply bars as supporters only, and change them two or three times: or else make use of the following method, applicable to large magnets. If the poles of such are to be changed, the middle of the end of the piece of iron placed at each end of the magnet (see *Armed MAGNET*) is to be placed against the end of the line designed to be the axis. If the poles are to be converted, it should be done first by touching double, if a sufficient force of magnetical bars can be applied for this purpose: but if, by touching double, the poles will not be converted, place the magnet between two pieces of iron, then keeping them steady at their distance, remove the magnet, and connecting the pieces of iron by wedges of iron, that may not stand in the way of it, when it is to be put in its place again, apply the supporters as before, and putting the magnet in its place, take off the iron wedges. This may be done two or three times, if it be found necessary, re-touching the supporters every time. (See *Artificial MAGNET*.) It is well known, that lightning not only destroys, but reverses, in some cases, the poles of magnetic needles. 30. Hard iron tools, well tempered, when heated by a brisk attrition, as filing, turning, &c. will, while warm, attract thin filings, or chips of iron, steel, &c. though not when cold; though there are not wanting some instances of their retaining the virtue when quite cold. 31. The iron bars of windows, &c. which have stood a long time in an erect position, grow permanently magnetical; the lower end of such bars being the north pole, and the upper end the southern. 32. A straight bar of soft iron (*e. g.* one of two or three feet in length, and about $\frac{1}{4}$ ths of an inch in diameter), that has not stood long in an erect posture, if it be only held, in these parts of the world, in a vertical position, will become magnetical; and its lower end the north pole; as appears from its attracting the south pole of a needle; and the upper end the south pole, being capable of repelling the south pole: but then this virtue is transient, and by inverting the bar, the poles will shift their places. An iron bar of four or five feet in length, and above an inch thick, in this situation, will be capable of attracting a small bit of iron, or a common sewing-needle. The explanation of this curious phenomenon is as follows: Since, in these northern parts, the earth is possessed of a south magnetic polarity, the lowest part of the iron bar, by being nearest to it, must acquire the contrary, *viz.* the north polarity; the other extremity of the bar becoming a south pole. It follows, likewise, (and it is confirmed by actual experiment), that in the southern parts of the earth, the lowest part of the bar acquires the south polarity; that on the equator

the bar must be kept horizontal, in order to let it acquire any magnetism from the earth; and that, even in these parts of the earth, the most advantageous situation of the bar is not the perpendicular, but that a little inclined to the horizon. In short, in every part of the world, it must be placed in the magnetical line, *viz.* in the direction of the dipping-needle. If the iron bar, instead of being kept in the magnetical line, be placed in a direction perpendicular to it, then it will acquire no magnetism, because, in that situation, the actions of both poles of the earth upon each extremity of the bar are equal. If, instead of the above-mentioned two directions, the bar be placed in any other position, then it will acquire more or less magnetic power, according as it approaches nearer to the former or to the latter of the said two directions.

A bar of hard steel, or of hard iron, does not acquire any magnetism from the earth, like the bar of soft iron, because the magnetic power of the earth is weak, in proportion to that which is required, in order to render a steel bar magnetic. In order, therefore, to render the quality permanent in an iron bar, it must continue a long time in a proper position. But the fire will produce the effect in a short time: for as it will immediately deprive a load-stone of its attracting virtue, so it soon gives a verticity to a bar of iron, if, being heated red-hot, it be cooled in an erect posture, or directly north and south. Nay, tongs and pokers, by being often heated and set to cool again in a posture nearly erect, have frequently gained this magnetical property. It is a well-known proposition, that soft iron, or soft steel, acquires magnetism very easily, and loses it with equal facility; but that hard steel acquires that power with difficulty, and afterwards retains it obstinately. From the consideration of these properties, Mr. Cavallo was led to imagine, that if a piece of steel, whilst red-hot, were placed between magnetic bars, and whilst standing in that situation, cold water were to be suddenly poured upon it, so as to harden it, there might, perhaps, be obtained an artificial magnet much more powerful than what can be produced in the ordinary way; because the magnetic bars employed for such purpose would communicate a great degree of magnetic power to the steel when red-hot, and consequently soft, which power would be fixed upon the steel by the hardening.

In order to put this project to the trial, six magnetic bars were so disposed, in an oblong earthen vessel, as that the north poles of three of them might be opposite the south poles of the three others, forming two parcels of bars, lying in the same direction, and about three inches asunder, which was nearly the length of the steel bar which was intended to be rendered magnetic. Things being thus disposed, the steel bar was made quite red-hot, and in that state was placed between the magnetic bars; after which, cold water was immediately poured upon it, which rendered it so hard as not to admit being filed: its magnetism was found to be considerably strong, but by no means extraordinary. From repeated trials with steel bars of different sizes, and by using a greater or less number of magnetic bars, Mr. Cavallo found that short steel bars acquire a proportionally greater degree of magnetism, by this method, than those which were longer; that the magnetism in the longer bars is not proportionally as strong, principally because the artificial magnets, being placed at their extremities, have very little power on those parts of the pieces of steel which are near its centre; and, lastly, that when, in order to remedy the just-mentioned inconvenience, more magnets are placed nearer the middle of the steel bar, then this piece of steel generally acquires many successive magnetic poles.

Upon the whole, it seems that though this method alone

M A G N E T.

be not sufficient to communicate to steel bars an extraordinary degree of magnetism, yet it may be of great use in constructing large artificial magnets; for, if these bars, instead of being hardened in the usual way, by plunging them, when red-hot, in water, be hardened whilst standing between powerful magnets, they will thereby acquire a considerable degree of magnetic power, without any additional trouble to the workman. They may then be polished, after which they may be rendered more strongly magnetic by the usual method of touching them with other magnetic bars; whereas it is a very laborious operation to render magnetic large bars of hardened steel from the very beginning, *viz.* when they have none of that power.

In the course of performing these trials, Mr. Cavallo frequently observed that the pieces of steel, whilst they were red-hot, seemed not to be attracted by the magnets; so that the least shock, and even the pouring of the water, could remove them from the proper situation, which rather surpris'd him; because it has been asserted by some authors, that the magnet attracts red-hot iron as well as cold. Kircher especially says, that he tried the experiment, (*De Magnete*, lib. i. p. 2, theorem xxxi.) and found that the piece of iron, heated so as to be hardly discernible from a burning coal, was attracted by the magnet as easily as when cold; and he even assigns a reason why the power of a magnet is destroyed by a great degree of heat; whereas the red heating of the iron will not prevent its being attracted by the magnet. The reason he gives is, that the fire corrupts and calcines the magnet, but purifies the iron. The following experiments were made in order to ascertain this matter:

“ I kept (says Mr. Cavallo) a piece of steel in the fire till it was quite red-hot, and in that state presented the magnet to it, so as to touch it repeatedly in various places; but no sign of attraction could be perceived before the redness disappeared. I mean, however, such redness as may be evidently seen in the clear day light; for, as was shewn by other experiments, when the magnet begins to attract the heated iron, the redness of the latter can still be seen in the dark.

“ Having repeated the experiment with different pieces of iron and of steel, the result was constantly the same, *viz.* whilst the iron or steel remained quite red-hot, or white-hot, the magnet did not attract it; but the attraction began when the degree of redness which is clearly perceivable in the day-light began to disappear; and it was as strong as ever when the iron was cooled a little more than when the redness quite disappeared in the dark. In regard to this limit, or maximum of attraction, I think I have observed, as well as the nature of the experiment would permit, a difference between steel and iron; which is, that in the steel the maximum of attraction follows the disappearance of the red heat sooner than in iron.

“ This experiment is subject to two sources of mistake, which, perhaps, misled father Kircher, and which it is necessary to mention, for the sake of others who wish to repeat it. The first is, that when a piece of iron, of no great extent, is red-hot, or even white-hot, in one place, and below a red heat in other parts, the magnet will frequently attract it, though the red-hot side be presented to it. The second cause of mistake is, that when a small piece of iron or steel, as a common sewing-needle, is made red-hot, and is then presented to the magnet, if the magnet touch it, the contact cools it instantly below the necessary degree of heat, and of course the attraction takes place. It is owing to this last cause, that I have not yet been able to ascertain, whether the attraction between the magnet and the iron be quite an-

nihilated, or only diminished to a great degree, by rendering the iron red, or white-hot; so that I can only say with certainty, that a magnet will not attract a certain piece of iron red-hot, or white-hot; whereas it will attract another piece of iron, at least fifty times bigger, if it be cold, or below a red heat.

“ To try this experiment in a different and more convincing manner, I heated a large iron nail till it was white-hot, and in that state placed it upon an earthen support, near one pole of the magnetic needle, so as to lie, not in the same direction, but on one side of it. Then, looking attentively on the graduated circle of the compass, I observed, that the needle was not in the least moved from its natural situation, whilst the nail remained red-hot; but, as soon as the redness began to disappear, the needle advanced towards the nail, and a few seconds after the needle pointed directly towards it.

“ I tried whether, in this experiment, any difference was occasioned by the magnet's being natural or artificial; but, as it might be expected, there was none.

“ In pursuance of those magnetic experiments wherein heat is concerned, I tried the effects which took place when the magnet was heated; but, as the diminution of its power by heating, and an increase of it by cooling, were observed and described by the late Mr. Canton, (*Phil. Transf.* vol. li.) I shall only add a circumstance, which may perhaps be new. It is, that an artificial magnet, after having had its power diminished by heating, does not recover it entirely again by cooling; having constantly found, that the magnets which had been heated, after cooling would never hold so great a weight of iron as they did before. The heat to which those magnets were exposed never exceeded that of boiling water. This was rendered more evident by the following experiment.

“ A magnetic bar was placed in an earthen vessel, at some distance from the south pole of the needle of a very good compass; by the action of which magnet, that end of the needle was drawn several degrees from the magnetic meridian, or from the direction in which it stood before. In this situation of the apparatus, boiling water was poured into the vessel wherein the magnet stood, in consequence of which the needle went back two degrees and a half. Some time after, when the water was quite cold, the needle was found nearer to the magnet, but not so near as it stood before the hot water was poured into the vessel.”

33. Mr. Boyle found, that by heating a piece of English ochre red-hot, and placing it to cool in a proper posture, it manifestly acquired a magnetic virtue. And an excellent magnet of the same ingenious gentleman's having lain near a year in an inconvenient posture, had its virtue surprisingly impaired; as if it had been injured by fire. 34. A needle well touched, it is well known, will point north and south: if it have one contrary touch of the same stone, it will be deprived of its faculty; and by another such touch, it will have its poles quite changed. 35. If a bar of iron have gained a verticity by being heated red-hot, and cooled again, north and south, and then hammered at the two ends; its virtues will be destroyed by two or three smart blows on the middle. Mr. Martin says, that by a smart stroke of a hammer on the untouched end of the dipping-needle, he has often caused the whole magnetic virtue to come to that end from the other, so as to make it dip on that side as much as it did on the other before: on the contrary, by such a stroke he has sometimes made it dip much more on the touched end than before. Sometimes, by striking it, the needle, which dipped before, will be reitored to its equilibrium, as if the virtue had

had

M A G N E T.

had made its escape, or were uniformly diffused all over the needle. 36. By drawing the back of a knife, or long piece of steel wire, &c. leisurely over the pole of a load-stone, carrying the motion from the middle of the stone to the pole; the knife or wire will accordingly attract one end of the needle: but if the knife or wire be passed from the said pole to the middle of the stone, it will repel that end of the needle which in the other case it attracts. 37. Either a magnet or a piece of iron being laid on a piece of cork, so as to swim freely in water; it will be found, that whichever of the two is held in the hand, the other will be drawn to it: so that iron attracts the magnet as much as it is attracted by it; action and re-action being always equal. In this experiment, if the magnet be set afloat, it will direct its two poles to the poles of the world. 38. A knife, &c. touched with a magnet, acquires a greater or less degree of virtue, according to the part it is touched on. It receives the strongest touch, when it is drawn leisurely from the handle towards the point over one of the poles: and if the same knife thus touched, and thus in possession of a strong attractive power, be retouched in a contrary direction, viz. by drawing it from the point towards the handle over the same pole, it immediately loses all its virtue. 39. The attraction of iron towards the magnetic needle, or magnet, is increased to a certain degree by the action of vitriolic acid. The experiment, ascertaining this fact, is stated by Mr. Cavallo, who made the discovery of it, as follows: some pieces of iron, as filings, nails, &c. are put into an earthen pot, and the pot is placed laterally near one end of a sensible magnetic needle; in consequence of which, that end of the needle will be drawn away from its natural direction, and will approach the pot more or less, according to the quantity of iron and vicinity of the pot. In this situation, if diluted vitriolic acid be poured upon the iron in the pot, so as to occasion a brisk effervescence, the needle will be found to come nearer to the pot during some minutes, after which it will gradually recede. This increased attraction is more or less, according to the quantity, surface, and vicinity of the iron, according to the briskness of the effervescence, &c. but with two or three ounces of iron filings, or with about six ounces of nails, and a suitable quantity of diluted vitriolic acid, the needle may be expected to make a movement from about 15' to half a degree.

“When I first observed this phenomenon, I naturally suspected (says Mr. Cavallo) that the increased attraction might have been caused by a quantity of iron filings being brought by the violence of the effervescence nearer to that side of the pot which stood towards the needle; and to avoid this source of mistake, I tried the experiment with a single piece of wire instead of filings, and twisted the wire in various directions, so as to be admitted into the pot. This experiment was several times repeated then, and also very lately, and the iron was used in various forms, viz. nails, turnings, pieces of wire, &c. but the result has been invariably the same, namely, an increased attraction.” Mr. Bennett has questioned the fact. See Phil. Trans. for 1792, p. 33.

40. Natural magnets may be imitated in the following manner: Take some martial æthiops, or, which is more easily procured, reduce into very fine powder the scales of iron, which fall from red-hot iron when hammered, and which are found abundantly in smith's shops. Mix this powder with drying linseed oil, so as to form it into a very stiff paste, and shape it in a mould so as to give it any form you require, whether of a terrella, a human head, or any other. This done, place it in a warm place for some weeks, and it will dry so as to become very hard. Then render it

magnetic, by the proper application of powerful magnets, and it will acquire a considerable power.

We shall here subjoin some additional observations on the subject, extracted from the laws of magnetism, proposed by Mr. Whiston. An inclinatory, or dipping-needle, of six inches radius, and of a prismatic, or cylindrical figure, when it oscillates along the magnetic meridian, performs, according to Mr. W. every mean vibration in about 6' or 360''; and every small oscillation in about 5½'', or 330''; and the same kind of needle, four feet long, makes every mean oscillation in about 24'', and every small one in about 22''.

The entire power of magnetism in this country, as it affects needles a foot long, is, as he says, to that of gravity nearly as 1 to 300; and as it affects needles four feet long, as 1 to 600. And the quantity of magnetic power accelerating the same dipping needle, as it oscillates in different vertical planes, is ever as the cosines of the angles made by those planes, and the magnetic meridian, taken on the horizon.

Thus, if we would estimate the quantity of forces in the horizontal and vertical situations of needles in London, we shall find that the latter, in needles a foot long, is to the entire force along the magnetic meridian, as 96 to 100; and in needles four feet long, as 9667 to 10000: whereas in the former, the entire force in needles a foot long is as 28 to 100; and in those four feet long, as 2569 to 10000. Whence it follows, that the power by which horizontal needles are governed in these parts of the world, is but one quarter of the power by which the dipping needle is moved.

Hence, also, since the horizontal needle is moved only by a part of the power which moves the dipping-needle; and that it only points to a certain place in the horizon, because that place is the nearest its original tendency of any its situation will allow it to tend to; whenever the dipping-needle stands exactly perpendicular to the horizon, the horizontal needle will not respect one point of the compass more than another, but will wheel about every way uncertainly.

The time of oscillation and vibration, both in dipping and horizontal needles equally good, is as their length directly; and the actual velocity of their points along their arcs is always equal.

Hence magnetic needles are, *ceteris paribus*, still better, the longer they are; and that in the same proportion with their length.

MAGNET, in *Medicine*. Some writers of the middle ages have, from a mistaken translation of Theophrastus, been induced to account the load-stone poisonous, which the ancients were so far from doing, that they gave it inwardly. Galen ascribes a purgative quality to it, and recommends it in drop-sies; and Dioscorides prescribes it as a good medicine to evacuate gross melancholic humours. It is doubtless possessed of the same virtues with the other ores of iron, though in modern times never used inwardly, having been only made an ingredient in some plasters. To these plasters very extraordinary virtues have been ascribed; such as that, when applied to wounds, they would extract iron, or even a knife, from the human body. See several similar stories in Kircher's “*De Magnete*,” who was too wise to give them any credit. The chemists are said to have been able to extract an oil of wonderful efficacy from the magnet, and to have made with it several preparations.

It has been said, that the application of the artificial magnet, or of a magnetical bar, to the teeth, will effectually cure the tooth-ache, that it will ease the pains of parturient women, that it will disperse white swellings, &c.; and,

M A G N E T.

on the contrary; that the wounds made with a knife, or other steel instrument, which has been previously rubbed with a magnet, are mortal. It is hardly necessary to add, that none of these pretended medicinal or poisonous qualities in the magnet are warranted by authentic facts: and as magnetism does not affect the smell, the taste, or any other sense of the body, it is improbable, to the greatest degree, that it should have any effect upon animal bodies. For though there are, without doubt, particles of iron in almost every part of an animal body, yet these particles are so subdivided and calcined, and bear so small a proportion to the other elements, that, in a natural state, the magnet has no action upon them.

MAGNET, in *Metallurgy* and *Chemistry*. Iron ores may generally be discovered to be such by the magnet; for almost all of them will be attracted by it either before or after ignition. A strong artificial magnet, well hung, and used as a needle, will best serve for this purpose. It will also readily find, and separate any little bits of iron or steel from other things, and particularly iron or steel from those of other metals. It will likewise discover whether tools, &c. are made of steel, or whether they are iron case-hardened; for the steel will receive a strong touch, when the other will hardly receive any. For the use of the magnetic needle, in *Mining*, see **NEEDLE**. According to Neumann, the magnet is almost totally soluble in spirit of nitre, and partially in the vitriolic and marine acids. See **IRON**, *Ores of*.

MAGNET, *Armed*, denotes one that is capped, cased, or set in iron or steel, in order to make it take up a greater weight, and also more readily to distinguish its poles. As both magnetic poles together attract a much greater weight than a single one, and as the two poles of a magnet are generally in opposite parts of its surface, in which situation it is almost impossible to adapt the same piece of iron to them both at the same time; therefore it has been commonly practised to adapt two broad pieces of soft iron to the poles of a load-stone, and to let them project on one side of the magnet, because in that case, the pieces of iron being rendered themselves magnetic, another piece of iron could be conveniently adapted to their projections, so as to let both poles act at the same time. Those pieces of iron are generally held fast upon the magnet by means of a brass or silver box. The magnet in this case is said to be *armed*, and the pieces of iron are called the *armature*.

In *fig. 7. Plate VI.* A B represents the magnet; C D, C D, represent the armature or pieces of iron, the projections of which are D, D, and to which the piece of iron, F, is made to adhere. The dots E C D C D represent the brass box, having a ring, E, at its upper part, by which the armed magnet may be suspended. Thus the two poles of the magnet, which are at A and B, are made to act at D D, where the straight piece of iron, F, may be conveniently applied.

For this purpose, and to avoid the armature, artificial magnets have been made in the shape of a horse-shoe, having their poles in the truncated extremities; for which reason they have more power than the straight magnetic bars.

When a piece of natural magnet is required to be armed, the first operation is to find out its poles; then let the magnet be properly shaped, *viz.* either in the form of a terrella, or in the more usual one of a parallelepipedon, in which latter case care must be had to let the poles fall about the middle of two opposite surfaces, in which direction the magnet ought to have the greatest length possible; it having been often observed, that a natural magnet is weakened in power much more by cutting off a part of its length,

in the direction of the poles, *viz.* so as to make the magnetic axis shorter, than in any other direction.

After having shaped the magnet properly, let two plates of soft iron be made, equal in breadth to those surfaces where the poles stand, and to project a little way on one side of the stone, as shewn in the figure. Those projections D, D, must be much narrower than the breadth of the plates. For magnets smaller than one ounce, the lower surfaces of the projections, to which the iron, F, is to be applied, need not be larger than about one-tenth of an inch; and from a quarter to half an inch is sufficient for larger magnets.

The thickness of the plates C D, C D, must be proportioned to the power of the magnet; there being a certain size which is the properest for any magnet, a larger or smaller thickness than which being not so advantageous. This thickness cannot be easily determined without actual trial; hence the best way is to make them very thick at first: then filing a little off, and examining the power of the magnet alternately: for the power increases gradually till a certain degree, at which limit the filing ought to be discontinued.

It is indifferent whether the armature be kept on by tying, or by a box; whether of metal or of wood; but as the box is the most permanent, this ought to be preferred: and it may be made of any metal excepting iron or steel.

When the magnet is spherical, the armature, or pieces of iron, must be adapted to that surface, and each to cover about a quarter of it.

What has been here said about the natural magnet, is equally applicable to the artificial ones; so that many magnetic bars may be joined together, and may be armed so as to form a very powerful *compound magnet*.

The armature rather strengthens the power of the magnet, for the same reason for which a piece of iron affixed to a magnet tends to render it more powerful.

If the artificial magnets be made in the shape of a horse-shoe, or of a semicircle, then there is no need of the armature, it being sufficient to join them together, either by rivetting or by a box; and, indeed, even with straight bars, the compound magnet may be made without the armature; but then, as the two magnetic poles cannot act in the same plane, it is proper to have two of those compound magnets, for the purpose of giving more conveniently magnetism to other bodies.

By this means the late Dr. Gowin Knight constructed two very powerful artificial magnets, or magazines of magnetic bars, which are now in the repository of the Royal Society. Each of these magazines consists of 240 bars, disposed in four lengths, so as to form a parallelepipedon, every length containing 64 bars. All these bars are kept together by means of iron braces, and the whole is suspended upon pivots and a proper wooden pedestal or carriage, so as to be easily placed in any required position. For a farther description of those magnetic magazines, see the *Phil. Transf.* vol. lxxvi. p. 591.

Mr. Michell directs to increase the power of a natural magnet, if it be small and short, by laying a great number of iron bars at its ends, after the manner of supporters, care being taken to apply the proper poles: if it be pretty long, so as to allow room for it, by touching it also double with several bars, according to its bulk, applying them to all sides at once. To increase the power of a large magnet, instead of placing supporters, he advises to put a large piece of iron, of the thickness and breadth of the magnet, at each end of it. This piece of iron should be either three or four times as long as it is thick, or else short, and three or

four times as large at the end not touching the magnet, as at the other: in the former of these ways, there are to be placed on one side, in the other case at the broad end, as many supporters as can conveniently stand there. This, if the magnet be very short, may be sufficient; if it be long, it should besides be touched double. If the magnets to be thus improved be very susceptible of magnetism, they should have much thicker armour than is generally used, because they will thus retain more magnetism; and the armour should be so fastened, that the hoops, &c. used for that purpose may not stand in the way of applying any thing to the ends, or the sides; for it is much the best way to make any short magnets magnetical in their armour, because they will retain more power by this means. But Mr. Michell apprehends, that the best way of managing very large magnets, would be to slit them, in a direction parallel to the axis, into several long bars of the length of the stone, and having made them magnetical singly, to put them into their armour, in the manner directed for compound artificial magnets. The steel bars used for artificial magnets may be armed and made magnetical, like the natural magnets. Armed compound artificial magnets may be made of several bars exactly of a length, with armour nicely fitted to them. The bars should have the same proportions as those of single unarmed magnets; they should be touched singly, and put into their armour, as they are touched, with the poles of the same denomination the same way. The armour should be pretty thick, and should have a wedge of iron applied to it, whilst the bars are putting in, and till the whole is bound together and finished; for which reason the case, that keeps the armour together at bottom, should be put on before any of the bars are in. The iron wedge should always continue applied to the magnet, but when it is used; for this will be a great preservation to it; though with all this precaution, it will lose a great deal of its first strength, in a very little time. Mr. Michell directs an occasional magnet of this kind to be made in the following manner: let there be a small box, about an inch deep, six inches long, and three or four wide; in the bottom of this box fix two bars of iron, at each end one, about $\frac{3}{4}$ ths of an inch square, reaching quite across the ends and through holes in one side, and projecting a little way beyond; these projecting ends serve as feet to lift with, like those of the common armed natural magnet: the faces of these feet should lie in the same plane with each other, and they may be reduced, by taking off the edges, to about half the breadth of the bar, in the flat way of the box. When the magnet is wanted, apply a wedge of iron to the two feet that come through the side of the box; and having made any number of the six-inch bars as magnetical as may be, place them one by one with their edges against the two iron bars in the box, and with their poles of the same denomination the same way, pushing them close against the side of the box, which will keep them from turning over and lying flat-ways. Having placed as many of the six-inch bars as are required in this manner, lay two or three doubles of flannel, or something else that is soft and spongy, over them, and press them against the two iron bars with the lid of the box, and fasten it down. Such a magnet as this may be easily taken to pieces and retouched, and set together again, as occasion shall serve. A magnet of this kind, consisting of three dozen of six-inch bars, will lift fifty pounds avoirdupois.

The following experiment will shew in what circumstances a magnet can lift the greatest weight. Take a magnetic bar, and find by trial an oblong piece of iron, about four inches long, and of a weight little greater than the magnet

will support. It is plain, that if you affix this iron to one pole of the magnet, the moment you remove your hand, the iron will drop; but if, before you remove the hand, you present another larger piece of iron just under the lower extremity of the former, and within half or three-quarters of an inch from it, you will find that the magnet will then support that piece of iron which it could not support before, when a secondary piece of iron was not under it. In short, a magnet can lift a greater weight of iron from over another piece of iron, as an anvil, or the like, than from over a table.

The reason of which property is, that in the former case, the iron basis, or inferior piece of iron, becoming itself in some measure magnetic, helps to increase the magnetism of the first piece of iron, and consequently tends to increase the attraction between it and the magnet; which does not take place when the iron is lifted from over a table, or something else which is incapable of acquiring any magnetism.

In order to render this property more intelligible, suppose that a piece of iron be affixed to the north pole of a magnet; it is plain, that by the action of the magnet the part of it that stands next to the magnet has acquired a south polarity, and its other, or inferior extremity, has acquired a north polarity, the attraction being a consequence of this acquired magnetism, and being greater or smaller in proportion as that acquired magnetism is more or less powerful; consequently, whatever tends to increase that magnetism in the piece of iron, must likewise increase the attraction. Now, when another piece of iron is under the former, that other piece of iron, being within the sphere of action of the magnetic bar, becomes magnetic, and the part of it which is contiguous to the north pole of the magnet acquires the south polarity; but this is contiguous to the lower end, which is the north pole, of the first piece of iron, therefore it must increase that north polarity, and, of course, the south polarity of the upper end of the first piece of iron, which stands next to the magnet.

In fact, if, instead of the secondary piece of iron, you put the south pole of another magnet at a little distance below the lower extremity of the suspended iron, you will produce the same effect, *viz.* will increase the attraction between it and the north pole of the first magnet; but if you present the north pole of the second magnet under it, then you will produce the contrary effect, *viz.* will weaken its magnetic power, and, of course, diminish the attraction.

The variable power of a magnet may be shewn by suspending iron to it, in the following manner. Suspend a magnet in a place that is not much shook, and apply to it as much weight of iron as it will just support. For this purpose, the magnet, either natural or artificial, ought to be armed, or made in the shape of a horse-shoe, *viz.* so as to have the poles in one plane; in this form the effect being more conspicuous. Let a hook or a scale, like those used for a balance, be fastened to this iron. On the day following, you may put a little more weight into the scale, which the magnet will support. One or two days after, a little more weight may be added; and so on; the power of the magnet increasing daily; and, though this increase of power is neither unlimited nor very regular, being affected in some measure by the vicissitudes of heat and cold, &c.; yet, upon the whole, the power of a magnet will be considerably increased by this artifice.

It is very remarkable, that if, in the course of the operation, the iron were to drop from the magnet, on replacing it, you will find that the magnet will no longer support as

MAGNET.

much weight as it did a moment before, so that now you must diminish the weight, though in the course of the following days you may increase it gradually again: hence, in placing the weights into the scale, or upon the hook, care must be taken not to give it any jerk, so as to cause the iron to fall off; otherwise a great deal of the work will be lost.

The reason of this experiment is, that the iron being rendered magnetic, tends to strengthen the magnetism of the magnet, in the same manner as any other magnet endeavours to render magnetic any ferruginous substance that is placed within its sphere of action. When the iron falls off, the magnet loses part of the acquired power, especially if the magnet had acquired more than its point of saturation, there having been removed the cause which kept it up; and when the iron is replaced, the magnet will not recover the lost power very readily, because there is required a considerable time to communicate a certain degree of magnetic power to a hard ferruginous substance, as the magnet is, especially when that magnetism must be communicated by the action of a proportionably weak magnet, like the iron weight.

According to *Æpinus's* hypothesis of the magnetic fluid, this experiment is explained thus: The magnetic fluid in a magnet is not equally dispersed through its substance; but one pole, or half of it, is overcharged, and the other undercharged: There is a strong attraction between the undercharged part and the superfluous quantity of magnetic fluid in the overcharged part, and the restoration of the balance is in great measure prevented by the hardness or some other quality of the magnet. Now, when the iron is affixed to the magnet, it becomes magnetic, *viz.* that part of it which is contiguous to the overcharged pole of the magnet, becomes undercharged, and the opposite one becomes overcharged. In this situation, the undercharged part of the iron, endeavouring to draw the magnetic fluid of the magnet towards itself, accumulates or draws it still nearer to that overcharged pole of the magnet; and, on the other side, the overcharged part of the iron being contiguous to the undercharged pole of the magnet, tends continually to drive the magnetic fluid away from that undercharged pole of the magnet; but the power of the magnet, according to the hypothesis, depends on the unequal distribution of the magnetic fluid, therefore the action of the iron, by endeavouring continually to increase that unequal distribution, must increase the power of the magnet.

It follows from this experiment, that a magnet is apt to lose much of its power when kept without any iron affixed to it.

MAGNET, *Arsenical*, *Magnes Arsenicalis*, in *Chemistry*, denotes a mixture of equal parts of arsenic, sulphur, and antimony, melted together over the fire, and condensed in manner of a stone.

It is a very gentle caustic, and was first invented by Angelus Sala. It succeeds very well in taking down fungous flesh in wounds. It has its name magnet, because, being worn during malignant diseases, it is supposed to preserve the wearer from infection, by a magnetical power.

MAGNET, *Artificial*, is a steel or iron bar, impregnated with the magnetic virtue, so as to possess all the properties, and be used instead of the natural load-stone.

Before we proceed to give a particular account of the various methods that have been practised for making artificial magnets, it may not be improper to premise some general observations on the communication of magnetism. We have already more than once had occasion to remark, that when a piece of iron or steel, or, in short, of any ferruginous body, is presented to a magnet, within a proper

distance of one of its poles, it becomes instantly magnetic the part of it which is nearest to the magnet acquiring the contrary polarity, &c.

This acquired magnetism is strongest with soft iron, and weakest with hardened steel, or with the brittle sort of cast iron; the other sorts of iron or ferruginous bodies acquiring a stronger or weaker power, according as they approach the hardness of the latter, or the softness of the former. But the permanency of the acquired magnetism follows just the reverse of this rule; so that the hardest steel retains it for many years with little or no diminution; whereas very soft iron loses it entirely the moment it is removed from the influence of the magnet; the other ferruginous bodies preserving it for a longer or shorter time, according as they participate more of the nature of hard steel, or of that of soft iron. Hence it may be deduced, that, in general, the best method of making artificial magnets consists in applying one or more powerful magnets to pieces of the hardest steel, because those pieces will thereby acquire a considerable power, and will retain it for a long time; taking care, in this operation, that the north pole of the magnet or magnets be applied to that extremity of the piece of steel which is required to be made the south pole, and that the south pole of the magnet be applied to the opposite extremity. In the same manner as a piece of steel or iron is rendered magnetic, a weak magnet may be rendered more powerful, or its power may be restored when lost.

It is evident, that in this method the operator should have one or more magnets, by the application of which the steel, or other ferruginous body, may be rendered magnetical; therefore it may be asked, by what means is magnetism originally given to such artificial magnets, as are said to have that power imparted without the interference of any magnet? The answer to this question is, that no magnetism at all can be communicated to any ferruginous body whatever, without the action of another magnet; and that, in the method vulgarly called, of giving magnetism to steel, &c. without the aid of a magnet, the beginning of the magnetic power is communicated from the earth, which is a real magnet; and, therefore, there is no magnetism communicated but by the action of another magnet. See art. 32, *supra*.

There are some particular circumstances which demand attention, in order to enable us to ascertain the best method of constructing artificial magnets.

1. The nature of the body must be adapted to the power which is to render it magnetic; remembering, that the soft ferruginous bodies both acquire and lose magnetism easier than those which are harder.

2. The shape of the bodies is to be considered next, experience shewing that an oblong one is in general preferable to any other. In case of steel bars, they ought to be quite hard, in order to acquire the greatest possible power, provided one has magnets sufficiently strong for the purpose; and if cylindrical, their diameters ought to be about one-fifteenth of their length; or, if not cylindrical, their thicknesses ought to be such as nearly to equal the weight of the cylindrical bars of the same length, and the diameter of which may be about one-fifteenth of their lengths.

3. Several magnets are much preferable to a single one, for the purpose of communicating magnetism; in the application of which, it must be remembered, that the south pole of the magnet produces a north pole in the part of the ferruginous body to which it is applied, and that the north pole of the magnet produces a south pole in the part, &c.

4. If it were required to construct a strong magnet, when the operator has either no magnet at all, or a very weak one, he must proceed gradually. It being impossible for a hard

M A G N E T.

and large steel bar to receive any sensible degree of magnetism from the action of the earth, or of any other weak magnet, the operator must begin with giving magnetism to several small and soft steel bars, impregnating one at a time by means of the weak magnet, or, if he have no magnet, by means of one or more iron rods properly situated, which in that case are real, though weak magnets. Then, by joining in a proper manner the small steel bars already made magnetic, he may communicate a stronger power to larger and harder steel bars; which will be capable of impregnating bars still larger; and so on.

It has been asserted by various authors, that if a short bar of soft steel be repeatedly stroked from end to end, in any situation, by a sufficiently long iron bar, likewise kept in any situation, the steel bar will thereby acquire a considerable degree of magnetism: from which it might perhaps be inferred, that there is no necessity of deriving the origin of magnetism from the earth. But an accurate investigation of this pretended fact has shewn, that the steel bar will not acquire magnetism in every situation. Indeed, as the bar of iron is rendered more or less magnetic by the earth in every situation, except that which is perpendicular to the magnetical line; in a random way of making the experiment, it is almost impossible to keep the bar so near that direction as to acquire no magnetism at all from the earth; but if, in rubbing the steel bar, the iron one be kept in a situation nearly perpendicular to that of the magnetical line, then the steel will acquire no magnetism at all. Besides, when the iron bar is kept in any situation, the degree of magnetism which is communicated to the bar, is greater or less in proportion as the direction of the bar is nearer to, or farther from that of the magnetical line; which proves, beyond a doubt, that the communicated magnetism is originally derived from the earth.

In order to make a piece of iron acquire magnetism from the earth, let the following process be pursued: Take a bar of soft iron, about two or three feet long, and between one-half of an inch and two inches thick, (such are some kitchen poker,) and place it in the magnetical line, *i. e.* in the direction of the dipping needle, if this be at hand, or straight up in higher latitudes N. or S. than 40° , but horizontally when nearer to the equator than the above-mentioned degree of latitude. Then place a magnetic needle on a pin, and holding the pin in your hand, present the needle to the various parts of the bar from top to bottom, and you will find, that in this island the lower half of the bar is possessed of the north polarity, capable of repelling the north and of attracting the south pole of the needle, and the upper half is possessed of the south polarity, capable of repelling the south and of attracting the north pole of the needle. The attraction is strongest at the very extremities of the bar; it diminishes as it recedes from them, and vanishes about its middle, where no one pole of the needle is attracted in preference to the other. In short, in that situation, the iron bar is as much a magnet as any piece of iron that stands within the influence of a magnet.

If you turn the bar top-side down, the extremity of it, which was south pole when it stood uppermost, will now become north pole, and the other extremity will become south pole.

In the southern parts of the world, the lower part of the bar is a south pole; or, to be more explicit, when in any part of the world the bar is situated in the magnetic line, the extremities of the bar will acquire the polarities corresponding to the nearest poles of the earth.

In order to fix in an iron bar the magnetism which the earth has communicated to it, the following circumstances

should be regarded. The very soft iron acquires the greatest degree of magnetic power in the shortest time, but loses it with the same quickness; so that, if the preceding experiment be performed with a bar of that sort of iron, the magnetism communicated to it by the earth will not be permanent; but if it be made red-hot, and be left to cool in the magnetic line, or if it be repeatedly struck with a hammer, whilst standing in the magnetic line, it will thereby acquire a small degree of permanent magnetism; which power, however, either by leaving the bar for some time in an improper situation, or by inverting and striking it again, will be soon destroyed.

When the iron is somewhat harder, the acquired magnetism lasts much longer; though a longer time, or longer operation, be required in order to render it magnetic.

As the constant action of a weak magnet on a ferruginous body continually tends to increase the magnetism of that body, so the iron bars, which are left in the direction of the magnetic line for a considerable time, become continually more strongly magnetic, and the acquired power becomes more permanent.

The reason why iron, by long standing, by hammering, &c. acquires a permanent magnetism from the earth, whereas by the mere position, in a short time, the power is not at all permanent, seems to be the unequal texture of the iron: suppose, for instance, that a piece of iron is composed of hard and soft particles, or of some, through which the magnetic power moves very easily, and others, through which it moves very slowly. The former then of those particles acquire the magnetism at first from the earth, and lose it very easily; but by continuing in the same position, or by being softened, &c. the hard particles gradually acquire magnetism from the former, and having once acquired it, retain that power for a long time. It is, besides, very probable, and in certain circumstances actually proved, that some sort of iron becomes harder by being kept long exposed to the atmosphere.

The method of making magnets of this kind, by means of a natural magnet, and even without the assistance of any magnet, was suggested many years ago by Mr. Servington Savery, and particularly described in the *Phil. Trans.* N^o 414. See also *Abridgment*, vol. vi. part ii. p. 260, &c. But as his method was tedious and operose, though capable of communicating a very considerable virtue, it was little practised. A more simple method was proposed by Mr. Arnold Marcel, nephew to Mr. Leuwenhoeck, and is described in the *Phil. Trans.* (See *Martyr's Abr.* vol. vi. part ii. p. 278.) It is as follows: "In the year 1776," says he, "making several further observations about the magnetical force which I found in great pieces of iron, I made use of a large iron vice, about 90lbs. weight, in which I fixed a small anvil of about 12lbs. Upon the bright surface of this anvil I laid the steel, to which I would give the virtue, in a position of north and south, which happened to be in a diagonal of the square surface of the anvil; then I took a piece of iron, one inch square, and 33 inches long, of about 5lbs. weight, having at one end the figure here represented (*fig. 8.*) brightly polished at A, and taper at the other end. Then I held fast down the piece of steel upon the anvil with one hand, and with the other I held the iron bar aforesaid perpendicular, with its point, A, upon the steel, and, pressing hard, I rubbed the steel with the iron bar towards me, from north to south, several strokes, always carrying the bar far enough round about, to begin again at the north, to prevent the drawing back of the magnetical force. Having thus given ten or twelve strokes, I turned the steel upside down, leaving it in the same position as to north and south, and,

after

M A G N E T.

after rubbing it and turning it, till I rubbed it about 400 times, it received by degrees more and more strength, and at last had as much as if it had been touched by a strong load-stone. The place where I began to rub, was always that which pointed to the north when the needle was hung, the end where I had ended the stroke turning to the south. Sometimes it has happened, that in a few strokes I gave the steel its virtue; nay, even in the very first stroke, one may give a great deal to a small needle. This way I have given the magnetical virtue to needles of sea compasses, made of one piece of steel, so strongly, that one of the poles would take up three quarters, and the other a whole ounce of iron. Although these needles were anointed with linseed oil, which made a hard coat; to keep them from rusting, yet they kept the virtue; but in strengthening these sorts of needles, I rubbed by turns first to the right and then to the left side.

“The same way I brought the virtue into the point of a knife, so that it would sustain $1\frac{3}{4}$ ounce.

“I brought the said virtue into four small pieces of steel, each one inch long, and $\frac{1}{4}$ th of an inch broad, as thin as the spring of a watch. These four pieces I joined together, as into an artificial load-stone, weighing 18 grains troy, and then it did draw up and sustain an iron nail, which weighed 144 grains troy. This artificial load-stone has now these six years been tumbled about, and been lying among iron and steel, and in any position, and yet it has rather got more than lost any of its virtue.

“The magnetical virtue being thus brought into iron or steel, I have farther observed, that that end where the stroke was begun, would draw to the north, and where the stroke ended, to the south, in whatever situation the steel had been laid upon the anvil to give it the virtue. I took a piece of steel, and rubbed it from one end to the middle, and then from the other end to the middle, and found it had two north poles, one at each end, and the middle a south pole.

“Further, beginning to rub from the middle towards each end of another piece of steel, I found it to have at each end a south pole, and in the middle a north pole.”

A very easy way of giving magnetism to a small piece of soft steel, is the following: Take two pokers of soft iron, or two iron bars, of about an inch square, and more than three feet in length, keep them in the magnetical line, or if in this island, perpendicularly, as shewn in *fig. 9*. Then let the piece of steel, C B, be either fastened to the edge of a table, or be held by an assistant; and placing the lower extremity of the bar A B, and the upper extremity of the bar C D, both on the same side, and in the middle of the steel, stroke the steel from the middle towards its extremities, moving the end of the bar, C D, from the middle of the piece of steel towards its end C, at the same time that the end of the bar, A B, is moving from the middle of the piece of steel to its other extremity B; and when the bars are arrived to the said extremities, remove them from the steel, and apply them again to the middle, and so on; thus stroking the piece of steel about forty or fifty times on every side, will give it a considerable degree of magnetism.

It is evident, that if in this experiment, when the iron bars are arrived to the extremities of the steel, you bring them back to the middle of it, by drawing them along the surface of the steel, the experiment will not succeed, because the magnetic power communicated by their rubbing the steel in one direction, will be destroyed by their contrary motion.

Dr. Gowin Knight was the first who brought this kind

of magnets to their present state of perfection, so as to be of much greater efficacy than the natural ones. The result of his method, though the process itself was kept secret, was first published in the *Phil. Transf.* for 1744, vol. xliii. art. 8, and *Phil. Transf.* for 1745, art. 3. See also vol. xlv. for 1747, art. 2. Mr. Wilson has communicated to the public Dr. Knight's method; who informs us, that having provided himself with a large quantity of clean filings of iron, he put them into a large tub, that was more than one-third filled with clean water: he then, with great labour, worked the tub to and fro for many hours together, that the friction between the grains of iron by this treatment, might break off such smaller parts as would remain suspended in the water for some time. The obtaining of these very small particles in sufficient quantity, seemed to him to be one of the principal desiderata in the experiment. The water being thus rendered very muddy, he poured the same into a clean earthen vessel, leaving the filings behind; and when the water had stood long enough to become clear, he poured it out carefully, without disturbing such of the iron sediment as still remained, which now appeared reduced almost to impalpable powder. This powder was afterwards removed into another vessel in order to dry it; and this process was several times repeated. When a sufficient quantity of this fine powder was procured, he made a paste of it with linseed oil; preferring this vehicle, because it contained a considerable quantity of the phlogistic principle. With these two ingredients he made a stiff paste, which he well kneaded, before he formed it into convenient shapes, and then upon wood, and sometimes on tiles, in order to bake or dry it before a moderate fire, at about a foot distance from it. In about five or six hours it generally attained a sufficient degree of hardness. When these baked pieces were become old, he gave them their magnetic virtue in any direction he pleased, by placing them between the extreme ends of his large magazine of artificial magnets for a few seconds or more, as he saw occasion. By this method, the virtue they acquired was such, that when any one of those pieces was held between two of his best ten-guinea bars, with its poles purposely inverted, it immediately of itself turned about to recover its natural direction, which the force of those very powerful bars was not sufficient to counteract. (*Phil. Transf.* vol. lxi. part i. for 1779, art. 5.) However, the method of making artificial magnets was discovered and published by Mr. John Michell, in a *Treatise of Artificial Magnets*, printed in 1750, and by Mr. John Canton, in the *Phil. Transf.* for 1751, vol. xlvii. art. 6, p. 31. The process for this purpose was also found out by others, particularly by Marul Uitgeleze *Natuurkund. Verhand.* tom. ii. p. 261, and Du Hamel, *Hist. Acad. Roy.* 1745 and 1750.

Mr. Michell's method of making magnets is as follows: prepare a dozen bars of steel, of about $1\frac{3}{4}$ ounce weight each, six inches long, and half an inch broad: let these be hardened with a full, but not too great heat: let one end be nicked all round with a chisel, to distinguish it from the other; and the ends of the bars should be cleaned after hardening, either upon a smooth stone, or razor-grinder's wheel: the size and shape of the bars may be varied at pleasure, provided that the length be proportioned to the thickness. The best sort of steel is that which has no veins of iron in it, and Mr. Michell has found the common blistered steel at least equal to any other. When any magnet does not answer expectation, it will be proper to harden it over again, with a greater or less degree of heat, till it proves better. In order to preserve these bars, contrive a box, that shall have two pieces of iron, about an inch long

M A G N E T.

each, fixed upright in the middle of each end, over against each other, at the distance of six inches from outside to outside. These pieces of iron may be about a quarter of an inch square, and should be filed pretty smooth on the sides. Against these are to be placed, with their edges towards them, the twelve magnetical bars, six on one side, with their south, or north poles one way, and six on the other side with the same poles the contrary way. It is necessary to observe that these bars must neither be taken out, nor put in, all, or too many on a side at once; for if two only be left, with their poles of the same denomination the same way, without one or more on the other side to counter-balance their effects, they will damage each other: and if two of the same side be taken out together, or laid with their poles of the same denomination together, after they are taken out they will also damage one another: and if this be the case it will be proper to restore them before they are used, after the manner prescribed for making of magnets. In order to make the marked ends of these bars south poles, and the other ends north poles, place six of them in a line north and south, bringing the unmarked end of one, to touch the marked end of the next throughout; the marked ends lying towards the north, which will be some advantage to them. Then take an armed magnet, and placing it with both poles upon one of the bars, the north pole towards the marked end, which is to be a south pole, and the south pole towards the unmarked end, which is to be a north pole, slide it backwards and forwards from end to end of the whole line of bars three or four times, taking care that they all touch. Then taking it off, remove the two endmost bars into the middle, and pass over them again three or four times. Having thus touched the bars, it will not be improper to turn them with the other side uppermost, and to touch them over again on that side as before, omitting the endmost bars, till they are removed into the middle, where they also are to be touched.

If an unarmed magnet, either natural or artificial, be used, lay the bars in a line as before; place the south pole of the magnet upon the marked end of the endmost bar, and slide it over the whole line to the end: then taking that pole off, place the north pole upon the same bar in its room, not at the extremity of the bar, but towards the middle, and slide it back again; then change the poles again, observing to set the magnet on at the middle of the bar, and slide it to the other end, as at first. Having done this four or five times, remove the two endmost bars into the middle, and placing the south pole of the magnet upon the marked end of them, slide it to the unmarked end; and then, placing the north pole upon the unmarked end, slide it to the marked end. Let this be repeated three or four times; and turning the bars with the other side upward, repeat the same process again. When the magnets are weak, it may be necessary to touch the bars, according to the preceding direction, before they are hardened, when they will receive the magnetic virtue more easily; then, making the whole dozen magnetical, in the manner hereafter prescribed, till they are as strongly so as they will be in their soft state, harden one half; and having made these again magnetical with the remaining half that are soft, harden those also, and proceed. But if the magnets are too weak to perform properly, even in this case, recourse must be had to smaller bars of steel, which should also be soft; and if these fail, bars of iron must be used. Having communicated a small degree of magnetism to six of the bars, let the other six, which are unmagnetical, be laid in a line, in the same manner as the former: and let A, B, (Plate VI. *Magnetism*, fig. 10.) represent this line, consisting of six bars, though three only are delineated. The line

drawn across at the end of each bar, represents the mark distinguishing that end which is to be made the south pole, from the other. Let C, D, E, F represent the six bars already made magnetical: these lean against each other at the top, and are separated by a piece of wood, or other matter except iron, about the tenth of an inch at the bottom. The three magnets in C, D have all their south poles downward, and are placed towards the unmarked ends of the bars in the line which are to be north poles; and the three magnets in E, F have all their north poles downward, and are placed towards the marked ends of the bars which are to be south poles. Slide these six magnetical bars thus placed, backward and forward three or four times over the whole length of the line. Then taking them off, having first brought them to touch at the bottom, remove the two endmost bars of the line into the middle, and replacing the magnetical bars upon them, as before, pass over those again. Then taking them off, and turning the bars in the line with the other side upward, go over them again in the same manner, excepting the endmost bars; which, when those in the middle are touched, are to be removed thither, to be touched in their turn. Thus the bars in the line will give a stronger power to that of the other six, by which they were touched; and, therefore, these latter may now be laid down in a line, and retouched, after the same manner, with the latter: when this is done, lay those down again, and retouch them with the others: repeat this operation a few times, first touching one set, and then the other, till they have acquired as much magnetism as they will retain; or till they will receive no additional force by any farther repetition. The six-inch bars, made magnetical after this manner, when properly hardened, will singly lift, by one pole, a piece of iron, weighing a pound or better, if it be of a proper form; and six such bars will touch a line of fresh bars of the same size, to their full perfection, by three or four times sliding over them; except the endmost, which must always be removed into the middle. As several magnets laid together with their poles of the same denomination the same way, will greatly injure one another, unless they have something to counteract them, it is absolutely necessary not to place two of them, of a side, or together; but singly, one on one side, and one on the other, making them to lean together, that they may rest against one another at the top: at the bottom they are preserved from injuring one another, by being placed upon the bar which is to be made magnetical. In like manner, they must not be taken off two of a side together, but singly, first on one side, and then on the other. But the readiest way of taking them off is first to bring them to touch one another at the bottom, in the same manner as they do at the top, and then they may be removed at once, and upon occasion set on again; only observing not to separate them again at the bottom, till they are placed upon the bar which they are to touch. The reason of removing the two bars at the ends of the line, in order to their receiving a greater virtue, seems to be, that the six magnets, employed in touching, are endeavouring to make that part of the bar which is not included between them magnetical, in a contrary direction from that which is included between them. As this last is the direction of magnetism designed, the former endeavour would be injurious; and it is prevented by two causes: one of which is the power, whereby the steel resists in a degree every endeavour, either to make it magnetical, or to destroy its magnetism; and the other is the power of the bars already in some measure magnetical, which lie at both ends of the bar that is touched. Now this last power is wanting at one extremity of those bars that are placed at the ends; and consequently not having a sufficient force fully to resist the contrary endeavour

M A G N E T.

your of the magnets employed in touching them, they become less magnetical than the others, which have a sufficient force. Though in the line of bars, when making magnetical, each bar has only one at each end to support it (those magnets that are planted at the ends of the others to preserve them being called supporters) against the contrary endeavour of the fix, made use of to touch it; and this does very well; yet some will receive an additional force by being supported with larger magnets; or instead of these, two or three of their own size, at each end; those at the marked end all with their north poles touching it, and those at the unmarked end all with their south pole touching it. And because there will be two or three north poles, and as many south poles together amongst the supporters, at the other end from the bar to be touched, that have nothing to counteract them, it will be proper to place the south pole of another magnet among the north poles, and the north pole of another among the south poles, that they may not hurt one another, which they otherwise will do.

The manner above described is called the *double touch*: and Mr. Michell observes, that two magnets will give more strength to a bar of their own size, when used after this manner, than a single magnet equal to five of the former in strength, when applied after the manner of the simple touch. This ingenious writer has described a frame, contrived for holding several of the six-inch bars, when they are used in touching large bars, and when they cannot be conveniently held in the hand; for an account of which we must refer to his excellent pamphlet, already cited, p. 45, &c. ed. 2. He observes, that the form of magnets is of very little consequence with regard to their receiving the magnetic virtue, provided that they have a sufficient length in proportion to their bulk. The straight bars may be made square, round, or flat: though the flat are most convenient for touching; and probably somewhat stronger. These may also be pointed at the ends, as in *fig. 11*, in order to render them lighter, and to increase their power of lifting; though pointed bars are not so proper for touching. The magnet may be made in the form of a horse-shoe, as in *fig. 12*, where a wedge of iron is supposed to be applied to the poles of it; and it will thus lie in a narrower compass, a wedge of iron may be applied to its two poles, and it will lift by both poles at once. The magnet may be also made annular, which is a plain flat bar, bent flatways instead of edgeways; and a semicircular magnet may be bent flatways, like the annular, or edgeways, like the horse-shoe; and two magnets of this kind may be conveniently placed together, in order to preserve each other.

The poles of a magnet may be converted by placing the bars which are to retouch it, with their north poles towards its north pole, and the south poles towards its south pole. In doing this, they should be placed on at the middle, and slid once or twice backwards and forwards, before it is supported; and then that which was the north pole must be supported as a south pole by north poles: and that which was the south pole, as a north pole by south poles. In order to make a bar magnetical, so that it shall have several poles, support it at the places where the poles are designed to be, with poles of a contrary denomination from those designed; and if any place is supported with south poles, the next places on either side must be supported with north poles, and *vice versa*. Having done this, consider each piece included between any two sets of supporters, as a separate bar, to be made magnetical, with its south pole towards the north set of supporters, and its north pole towards the south set, and touch it accordingly. Magnets of this sort will not do well, unless they are very long; and at best they are always weak, and

will very soon be injured; so that they should only be made occasionally.

Mr. Michell has also published a method of obtaining magnetism by means of three iron bars, without the assistance of a natural load-stone, for which we shall refer to his pamphlet, p. 60, &c. and proceed to describe the method described by the ingenious Mr. Canton.

This gentleman has succeeded so well in his attempts to convey a considerable magnetic virtue to bars of hardened steel, as to be able to impregnate such bars with this virtue to as high a degree, at least, as any bars of the same weight and dimensions, which he had seen or heard of; and to as high a degree, as he apprehends, the same bars, in their present state, are capable of being impregnated. Mr. Canton was able, in about half an hour's time, to communicate to six bars of hardened steel, at first entirely destitute of any magnetic virtue, the utmost virtue they were capable of receiving; and that without the mediation or assistance of any natural load-stone, or of any artificial magnet. Mr. Canton has published the description of his process with such directions, that any person may readily perform the same. For this purpose procure a dozen bars; six of soft steel, each three inches long, $\frac{1}{4}$ inch broad, and $\frac{1}{8}$ th of an inch thick, with two pieces of iron, each half the length of one of the bars, but of the same breadth and thickness; and six of the hard steel, each $5\frac{1}{2}$ inches long, $\frac{1}{2}$ inch broad, and $\frac{3}{8}$ ths of an inch thick, with two pieces of iron of half the length, but the whole breadth and thickness of one of the hard bars; and let all the bars be marked with a line quite round them at one end. Then take an iron poker and tongs, or two bars of iron, (*Plate VII. Magnetism, fig. 1.*) the larger they are, and the longer they have been used, the better; and fixing the poker upright between the knees, hold it to near the top one of the soft bars, having its marked end downward, by a piece of sewing silk, which must be pulled tight with the left hand, that the bar may not slide; then grasping the tongs with the right hand a little below the middle, and laying them nearly in a vertical position, let the bar be stroked by the lower end, from the bottom to the top, about ten times on each side, which will give it a magnetic power sufficient to lift a small key at the marked end; which end, if the bar was suspended on a point, would turn towards the north, and is, therefore, called the north pole, and the unmarked end is, for the same reason, called the south pole of the bar. Four of the soft bars being impregnated after this manner, lay the other two (*fig. 2.*) parallel to each other, at the distance of about one-fourth of an inch between the two pieces of iron belonging to them, with a north and a south pole against each piece of iron; then take two of the four bars already made magnetical, and place them together, so as to make a double bar in thickness, the north pole of one being even with the south pole of the other; and the remaining two being put to these, one on each side, so as to have two north and two south poles together, separate the north from the south poles at one end by a large pin, and place them perpendicularly with that end downward, on the middle of one of the parallel bars, the two north poles towards its south, and the two south poles towards its north end; slide them backward and forward three or four times over the whole length of the bar, and removing them from the middle of this, place them on the middle of the other bar as before directed, and go over that in the same manner; then turn both the bars with the other side upward, and repeat the former operation: this being done, take the two from between the pieces of iron, and placing the two outermost of the touching bars in their room, let the other two be the outermost of the

M A G N E T.

the four to touch these with; and this process being repeated till each pair of bars has been touched three or four times over, which will give them a considerable magnetic power, put the half dozen together after the manner of the four (*fig. 3.*), and touch with them two pair of the hard bars, placed between the irons at the distance of about half an inch from each other; then lay the soft bars aside; and with the four hard ones let the other two be impregnated (*fig. 4.*), holding the touching-bars apart at the lower end near two-tenths of an inch, to which distance let them be separated after they are set on the parallel bar, and brought together again after they are taken off; this being observed, proceed according to the method already described, till each pair has been touched two or three times over. But as this vertical way of touching a bar will not give it quite so much of the magnetic virtue as it will receive, let each pair be now touched once or twice over, in their parallel position between the irons (*fig. 5.*), with two of the bars held horizontally, or nearly so, by drawing at the same time the north of one from the middle over the south end, and the south of the other from the middle over the north end of a parallel bar: then bringing them to the middle again without touching the parallel bar, give three or four of these horizontal strokes to each side. The horizontal touch, after the vertical, will make the bars as strong as they can possibly be made; as appears by their not receiving any additional strength, when the vertical touch is given by a greater number of bars, and the horizontal by those of a superior magnetic power. This whole process may be gone through in about half an hour, and each of the larger bars, if well hardened, may be made to lift twenty-eight troy ounces, and sometimes more. And when these bars are thus impregnated, they will give to a hard bar of the same size its full virtue in less than two minutes; and will, therefore, answer all the purposes of magnetism in navigation and experimental philosophy, much better than the load-stone, which is well known not to have sufficient power to impregnate hard bars. The half dozen being put into a case (*fig. 6.*), in such a manner as that two poles of the same denomination may not be together, and their irons with them as one bar, they will retain the virtue they have received; but if their power should, by making experiments, be ever so far impaired, it may be restored without any foreign assistance in a few minutes. And if, out of curiosity, a much larger set of bars should be required, these will communicate to them a sufficient power to proceed with, and they may in a short time, by the same method, be brought to their full strength. Mr. Canton, by the same process, communicated magnetic virtue to two large bars, each half an inch square, 10½ inches in length, and weighing nearly ten ounces and twelve pennyweights, to such a degree, that one of them lifted by one of its ends seventy-nine ounces and nine pennyweights: and a flat semi-circular magnet, weighing an ounce and thirteen pennyweights, was made to lift, by applying its two ends together to an iron wedge, ninety troy ounces. The same ingenious gentleman could also readily deprive his bars of their virtue; and change the poles of a natural load-stone, by placing it in an inverted direction, between the contrary poles of his larger bars, laid down at some distance from each other, in the same straight line continued at the distance of about a quarter of an inch from either of the poles, without touching the stone with either of the bars.

The method in which the steel he made use of was hardened is as follows: having cut a sufficient quantity of the leather of old shoes into very small pieces, an iron pan is provided, which a little exceeds the length of a bar, is

wide enough to admit of two bars side by side without touching each other on the pan, and at least an inch deep. This pan is nearly half filled with the bits of leather, upon which are laid the two bars, having fastened to the end of each a small wire for taking them out: the pan is then quite filled with the leather, and placed on a gentle flat fire, being covered and surrounded with charcoal. The pan, being brought to somewhat more than a red heat, is kept about half an hour, and the bars are suddenly quenched in a large quantity of cold water. Mr. Horne, in his *Essays on Iron and Steel*, p. 147, claims the merit of directing this process for hardening Mr. Canton's bars.

In order to communicate the magnetic virtue to a steel bar, to the needle of a compass, &c. by means of two magnetic bars, place the bar or needle, A B (*fig. 7.*), upon a table, then place the two magnetic bars C D, E F, straight up upon A B, at a little and equal distance from the middle of the bar A B, and in such manner, as the south pole, D, of one of the bars may be nearest to that end of the bar, A B, which is required to become the north pole, &c. then these two bars must be slid gradually towards one extremity of the bar, keeping them constantly at the same distance from each other; and when one of the magnetic bars, for instance C D, is arrived at A, then they must be slid the contrary way, till E F arrives at B; and thus the bar, A B, must be rubbed a greater or smaller number of times, till it will be found by trial to have acquired a considerable power. When the magnetic bars are powerful, and the bar, A B, is of very good steel, and not very large, a dozen of strokes are fully sufficient. When the magnetic bars are to be removed from the bar A B, care must be had to bring them to the same situation where they were first placed, *viz.* at a little and equal distance from the middle of the bar A B, and then they may be lifted up.

In this operation, the effect of the bars may be improved several ways, which will be found necessary when the bar, A B, is proportionably large, and it is required to give it the greatest possible power. This may be effected, first, by joining the magnetic bars at top, interposing a piece of wood or other substance, except iron, to keep them apart, as shewn in *fig. 8*; for in this manner, the upper poles of the bars being contiguous, will tend to strengthen each other, and, of course, their lower poles will also be strengthened. Secondly, by placing the bar, to be rendered magnetic, between two bars of soft iron, or two other magnets, as shewn in *fig. 9*, or in the manner before directed. Thirdly, the magnetic bars may be inclined the contrary way, after the manner used by Mr. Apinus (*fig. 10.*); so that the magnets C D, E F, may make an angle of about fifteen degrees with the bar A B.

The bar, A B, may, in the same manner, be rendered magnetic by means of an armed magnet, as shewn in *fig. 11*; or by a horse-shoe magnet, as shewn in *fig. 12*, placing both the poles of the magnet in contact with the bar, &c.

In all these methods, the bar to be rendered magnetic must be stroked on every side; and, in order to let the magnetic centre fall just in its middle, care must be had to stroke one-half of the bar just as often as the other half.

Whenever a steel bar, or in general a piece of ferruginous substance, is rendered magnetic by applying two bars, or whenever two magnetic poles are applied to it at the same time, as used in this and the preceding experiment, the operation is usually called the *double touch*, in distinction from the *single touch*, which is when only one magnetic pole is applied to it.

As artificial magnets are frequently made in the shape of a femicircle, or like a horse-shoe, for the sake of bringing both poles in the same plane, the crooked steel bars of which they are constructed are made magnetic in the same manner as the straight bars, excepting only, that the magnetic bars which are used for it must follow the curvature of the steel bar; thus, if it be required to render magnetic the piece of steel A B C (*fig. 13.*), place it flat upon a table, and to its extremities apply the magnets D F, E G; joining their extremities F, G, with the conductor or piece of soft iron F G. Then apply the magnetic bars H, I, to the middle of the piece A B C, and stroke it with them, from end to end, following the direction of the bent steel, so that on one side of it the magnetic bars may stand in the direction indicated by the dotted representation L K. In this manner, when the piece of steel has been rubbed a sufficient number of times on one side, turn the other side upwards, and repeat the operation till it has acquired a sufficient degree of magnetism.

In this operation, the same precautions must be followed as were recommended for the method of communicating the magnetism to straight bars, *viz.* the magnets D F, E G, as well as the magnets H, I, must be placed so that their south poles must be towards that extremity of the bent steel which is required to be made the north pole, and their north poles towards the other extremity. The magnets, I, H, must be first placed on the middle of the bent steel; and after having drawn them over one leg of it as often as over the other, in order to let the magnetic centre fall just in the middle of the bent steel, they are removed, &c.

If a person have only one magnetic bar, or a terrella, with which he wishes to give magnetism to a needle or other bar, the only way of effecting it is, to apply one pole of the terrella, or magnetic bar, A B (*fig. 14.*), to one extremity, C, of the needle, and to draw it all along the surface of it till it reaches the other extremity D; then the magnet being removed, must be applied again to the extremity C, and must be drawn over the needle as before. Thus the needle must be rubbed several times, by which means it will acquire a considerable degree of magnetism.

It must be observed, that the extremity of the needle which the pole of the magnet touched last, acquires the contrary polarity. Thus, in the present instance, if B be the north pole of the magnet, the extremity, D, of the needle will afterwards be found to have acquired the south polarity, and the other extremity, C, the north.

In this operation it is evident, that, after the first stroke, when the magnet is applied again to C, this extremity, having acquired the north polarity, will have that power destroyed by the vicinity of the north pole, B, of the magnet; so that it seems that every stroke undoes what was done in the preceding. However, the fact is, that by repeating the strokes the power is increased; but, in general, this method will never be so advantageous as when more than one magnetic pole is used: hence it ought not to be used, excepting in case of necessity, *viz.* when one has only one magnetic bar or terrella.

Artificial magnets are preferable to the natural ones in a variety of respects. Mr. Michell mentions particularly, that they may be had at much less expence and trouble, and in greater plenty; that they are much superior to natural magnets in strength, and better able to communicate the magnetic virtue in proportion to their strength; that they are more easily restored to their former strength when they are at any time damaged; that they furnish several poles; and that they may be had in every form. Cavallo's Magnetism. Cavallo's Philosophy, vol. iii.

MAGNETICAL AMPLITUDE, *Azimuth*, and *Declination*, see the several substantives.

MAGNETICAL Island, in *Geography*, an island in the South Pacific ocean, near the N.E. coast of New Holland, discovered by Capt. Cook in the year 1770, and so named from its seeming to have some effect on the compass. S. lat. 19° 8'. W. long. 213° 22'.

MAGNETICAL Line, is that line in which a needle would place itself, if left at entire liberty to turn itself as well vertically, as horizontally. See DIPPING.

MAGNETICAL Meridian. See MERIDIAN.

MAGNETICAL Needle. See NEEDLE. See also *Mariner's COMPASS*, DIPPING, and the article MAGNET.

MAGNETICAL Paradox. Upon the table A B (*Plate VI. Magnetism, fig. 15.*) place a piece of iron wire, not above a tenth of an inch long. Let the magnetic bar, E F, be held at about four or five inches above the table, with either pole downwards, and in such a place, as that the perpendicular let fall from it to the table may touch the table at G, *viz.* two or three inches distance from the iron wire: these distances, however, are subject to a good deal of variety, arising from the power of the magnet.

By the action of the magnet the iron wire will elevate one of its ends, as represented by C D, forming with the table an angle, which is larger the nearer the wire comes to the point G, where it stands quite erect.

In this situation, if you give gentle knocks to the table, the wire, C D, will gradually proceed towards G, every knock making it jump up and advance a little way. The reason of which a superficial observer would immediately attribute to the attraction between the magnet and the iron wire, which, being not sufficiently strong to raise the wire from the table, has just power enough to draw it a little nearer to the point G, when the motion of the table lifts it up.

Thus far the experiment shews nothing extraordinary; but if it be repeated with only this variation, *viz.* that the magnet, instead of being held above the table, be placed below it, *viz.* at H I, the event will be, that the wire, which will now make an obtuse angle towards G, as represented by K L, on knocking the table, will gradually recede from the point G, shewing as if the magnet repelled it; which has given to this experiment the name of *magnetical paradox*; for, in fact, the magnet attracts the wire.

This phenomenon results from the directive property of the magnet acting at a greater distance than the attractive.

In order to explain the immediate cause of this phenomenon, it must be considered, that the wire K L, (*fig. 16.*) being rendered magnetic by the action of the magnet H, is inclined to it according to the above-mentioned laws of the dipping needle; but, on account of its weight, and because it is supported not in its centre, but by one end, namely K, which stands upon the table, it does not incline so much as it ought to do, if it were freely suspended by its centre, the end, K, now being a little higher than its proper situation. Let M N be the perpendicular, which passes through the centre of the wire. Now, when by the motion given to the table, the wire is made to jump; this, whilst remaining in the air, will take its proper inclination, as shewn by r Q, its centre remaining in the same perpendicular M N; for the directive power of the magnet, H, acts at a greater distance than its attraction. In this situation it is evident, that a perpendicular P O, let fall from the lower extremity, r, of the wire, touches the table in a point farther from G than the point K; and as the wire after the jump comes down to the table again with the proper inclination, *viz.* parallel to r Q, it follows, that now its lower end must touch the table at O: and thus every knock

will

will force it to recede a little more from the point G, which lies just over the magnet H.

The same explanation applied to the first part of the experiment, will shew that the wire must in that case, *viz.* when the magnet is held above the table, approach continually the point G.

This experiment may be diversified by using iron filings, instead of the iron wire; for, in the first case, the filings dispersed over the table will be gradually collected about the point G; and in the latter case, the filings placed about the point, G, will be gradually forced to recede from that point. Cavallo's Magnetism, chap. vii.

MAGNETICAL Variation. See VARIATION and DECLINATION.

MAGNETIS LAPIS, in the *Natural History of the Ancients*, the name given in different ages to two very different substances. The earliest Greek authors expressed by it the load-stone, which became afterwards called *Heraclius lapis*, (see IRON, *Ores of*, and MAGNET); and then the word *magnes* was applied to a very different stone brought from the same place, the neighbourhood of Magnesia in Lydia.

This was a fine beautiful and bright substance, of a pure white, and so very bright and glossy, as to bear a resemblance to polished silver. It was dug in large masses, and was of a texture capable of being wrought into any figure. Accordingly it was in great esteem among the ancients, who had it wrought into vessels for the use of the table.

It seems to be wholly unknown at present among the nations we have commerce with. Hill's Theophrast. p. 79.

MAGNETISM, MAGNETISMUS, that quality or constitution of a body, and its pores, whereby it is rendered *magnetical*, or a magnet.

Magnetism is found to be a transient power, capable of being produced and destroyed again.

MAGNETISM of the Earth is that property of the terrestrial globe, from which the magnetism of the ordinary magnets, the direction of the magnetic needle, and other phenomena are derived, and upon which they necessarily depend. This hypothesis is evinced by so many observations, that no philosopher can be sceptical enough to dispute its truth. The principal reasons, says Mr. Cavallo, which prove it, almost to a demonstration, are, first, that almost all the phenomena which may be exhibited with a usual magnet, may be also exhibited with the earth, as far as it may be tried; and secondly, that vast masses of iron, or ferruginous substance, actually magnetic, are dug out of the earth almost in every part of it.

"The phenomena of the compass and of the dipping needle, in different parts of the world, and the magnetism naturally acquired by soft iron when properly situated, are exactly imitated by a common magnet, or a terrella; but the only phenomenon, which has not been observed with respect to the earth, and which is the principal property of the usual magnets, is the attraction of a piece of iron, or other ferruginous substance. For instance, if a piece of iron be presented to either of the poles of a common magnet, it will be powerfully attracted by it; but if it be presented to the middle of the magnet, the attraction will be found to be hardly perceivable, or at least incomparably weaker than at the poles; in conformity to which, it might be expected, that a piece of iron should be attracted more powerfully downwards, when near the poles of the earth than when near the equator; which attraction, being combined with the attraction of gravitation, ought to be known by the difference of the weights of the same piece of iron, when weighed near the poles, and when weighed near the equator; for, if the magnetic at-

traction of the earth upon it be at all sensible, it ought to weigh more in the former case than in the latter. But this difference of weights has not yet been ascertained; however, if it were to be tried with all the accuracy necessary for so nice an experiment, I am inclined to think that it would be found to answer; *viz.* that the same piece of iron would be found to weigh somewhat more in places nearer to the poles, than it does nearer to the equator: but, even in case no such difference of weights were observed, it would be improper to infer that the earth does not exert any magnetic attraction towards the iron on its surface, and that this attraction is not stronger near the poles than near the equator; because, first, the magnetism of the earth being very weak, the difference of the attraction in different places must be likewise very small, notwithstanding the directive power is considerably strong; for, as was explained under the article MAGNET, the latter of those powers extends to a much greater distance than the former. And, secondly, it must be considered, that the equatorial diameter of the earth is longer than its polar diameter, and that the attraction of gravitation, or the weight of bodies, decreases in proportion to the squares of the distances from the centre of the earth; in consequence of which, if we abstract the magnetic attraction, and consider only the attraction of gravitation, it will appear that the piece of iron must weigh more when weighed near the poles than when weighed near the equator; namely, because when near the poles, it stands actually nearer the centre of the earth than when near the equator.

"If the magnetic needle pointed always due north and south, or always within a certain distance of those points, it would shew that the earth has two fixed magnetic poles, either coinciding with its astronomical poles, or at some distance from the same; but the continual variation of the magnetic needle shews, that those magnetic poles of the earth move with respect to the surface of the earth, and, on this account, many suppositions have been offered to the public by divers ingenious persons. It was imagined, that there was a large magnet inclosed within the body of the earth, which being not fixed to the external part, moved with respect to it, and, consequently, occasioned the variation of the needle." To this purpose, Mr. Whiston alleges that the earth on which we live, includes within it a vast spherical magnet, concentric thereto, having its own poles, meridians, equator, and parallels; and all much of the same general nature of those with small terrellæ, or spherical load-stones, in the possession of the curious among us.

The power of a good terrella, or a spherical load-stone, says this author, as it affects a needle a foot long, is equal to the magnetic power of that internal load-stone about two and a half, or three diameters of such load-stone. From which consideration, the quantity of magnetic attraction at all distances from the internal load-stone, for needles a foot long, may be determined; and from the same consideration it appears, that the diameter of this internal load-stone is about eleven hundred and fifty miles. To which we add, that, in regard sir Isaac Newton has demonstrated, that the power of gravity diminishes within the earth, and is less there than at its surface, nearly in the proportion of its greater nearness to the centre, the magnetic power, at two thousand nine hundred miles distance from us, and nearly one thousand and sixty from the earth's centre, which is $\frac{1}{24}$ of the power of gravity here, will be somewhat greater than the power of gravity there; which limit is worthy our attention, gravity being stronger than magnetism on the one side of it, and weaker on the other; we mean, as it affects needles of one foot diameter. At that limit, therefore, at least

MAGNETISM.

least near the magnetic poles, iron a foot long will be twice as heavy, and fall twice as fast, as any other natural body, *viz.* by the union of those two equal powers, gravity and magnetism; and of consequence, above that limit, such an iron will be less than twice as heavy, below it more than twice as heavy, as any other natural body.

The earth's internal load-stone, he says, is not fixed to our upper parts, but is moveable with respect to them, and actually revolves on the earth's axis, from east to west, in a certain long period of time; as appears beyond contradiction, from the constant variation of the horizontal needle westward; as well as the regular increase of inclination of the dipping needle.

The only way to render this motion, *i. e.* the variation, possible and intelligible (to use Dr. Halley's words), is to suppose it to turn about the centre of a globe, having its centre of gravity fixed and immovable in the same common centre of the earth. This moveable internal surface must likewise be loose, and detached from the external part of the globe, which may be reckoned the shell, and the other the nucleus or inner globe, included within it, with a fluid medium between. Now, from the variation's moving westward, it is plain, that the foresaid nucleus has not precisely attained the same degree of velocity with the exterior parts in their diurnal revolution: but so nearly equals it, that in three hundred and sixty-five revolutions, the difference is scarcely sensible; and must probably have arisen from hence, that the impulse, whereby the diurnal motion was impressed on the earth, was given to the external parts, and thence communicated to the internal.

This internal magnet has one central pole northward, in the nature of the poles of our common load-stones; but its southern pole appears not to be central, but rather circular, and that at a great distance from the southern pole of the earth.

The northern magnetic pole is *now* situate, says Mr. Whiston, about the latitude of $76\frac{1}{2}$ degrees; *i. e.* $13\frac{1}{2}$ degrees from the north pole of the earth, and about 30 degrees eastward from the meridian of London.

The southern magnetic circular pole has its centre, or central pole, nearly in the parallel of 60 degrees; and, in a meridian passing along the east coast of Borneo, about 117 degrees eastward of London. Its radius is also an arc of a great circle of about 44 degrees.

The respective motion of the internal magnet, or the velocity, *v. g.* of its north pole, appears to be 27 deg. 0 min. in 144 years, *i. e.* upwards of one degree in five years; so that it makes an entire revolution in 1920 years. Hence, as the number of degrees in the upper earth's diurnal revolution is to the number of days in the revolution of the internal magnet, *i. e.* as 1 is to 700,000, so is the respective motion of this magnet from east to west to the real motion of the upper earth from west to east; or, to speak strictly, so is the difference of their motions from west to east to the entire motion of the upper earth the same way. This external fixed earth has therefore communicated almost all its motion already to the internal magnet; and can communicate no more than this difference of their motion, and that only in an infinite term of years; or, in other words, this real internal motion can never be the seven hundred thousandth part swifter than it is at present. This internal motion, therefore, began with the commencement of the diurnal motion of the upper earth; and has gone on still faster and faster by the communication of that motion through the intermediate fluid. Since, therefore, action and re-action are equal, and tend to contrary parts, this internal load-stone, thus accelerated by the upper part, must have all along re-

tarded that upper earth, and made the diurnal rotation still slower and slower. This acceleration on one side, and retardation on the other, must have been very great at the first beginning of the diurnal motion, when the difference of their motion was equal to the entire motion itself, and must have been diminishing ever since. To which cause is probably owing that acceleration of the moon's motion with respect to that of the earth, since the time of the old astronomers, first taken notice of by Dr. Halley, and embraced by Sir Isaac Newton. And the same consideration seems to suggest a method for determining the age of the world; for, were the proportions of the quantity of matter in the upper earth to the internal magnet, with the tenacity of the intermediate fluid, &c. known, one might go back from the known difference of their velocity now, and find those differences and quantities of motion themselves, *à priori*, in all past ages; or, were the velocity of the first diurnal rotation of the upper earth known, we might geometrically determine, *à priori*, how long ago that rotation began, or how ancient our earth is.

The variation of magnetic needles from the azimuth of the meridians of the internal magnet is derived, says Mr. Whiston, from the difference of the strength of the several parts of the internal magnet's surface; which as it is only to be known by experience, that variation cannot be determined before-hand, unless where there are good accounts how much it had formerly been; it being probable, that it returns round, and will be the same in any year of the next revolution of the internal magnet, that it has been in the like year of any former revolution, or will itself have a revolution in about 1920 years. Mr. Whiston adds, that the two fixed magnetic poles in our upper earth first introduced by Dr. Halley, as necessary to solve the irregularity of the variation of the horizontal needle from the meridians of the moveable internal magnet, seem not to have any just foundation in nature, the like irregularities being found in the common terrellæ, or spherical load-stones, and being best accounted for from the composition of the magnets, which are found to have parts of different degrees of purity, strength, and perfection; so that where the parts are weaker than ordinary, the stronger neighbouring parts prevail, and draw the needle that way: not but Dr. Gilbert's notion of prominent and depressed parts on magnets may have some room, and be allowed to contribute somewhat to such variations. See VARIATION.

On the supposition above stated, the variation ought to be regular; that is, it ought to move in all parts of the world, so as to answer to the two points of the large internal magnet; which, however, is not the case.

In order to supply the deficiency of this hypothesis, it was farther imagined, that there were four magnetic poles within the earth, which were moveable with respect to each other, and that, therefore, the variation of the needle ought to be derived from all their actions conjointly; which would render the theory of the variation exceedingly intricate: but, notwithstanding this difficulty, a regularity, within certain laws and limits, ought to be still observable respecting the variation; but no such regularity has been yet proved. In short, without detaining our readers any longer on this point, it will suffice to say, that no theory yet offered has been sufficient to foretel, with certainty, the variation of the needle for any future period of time, or for any place distant from those in which observations have been frequently made. See DECLINATION, COMPASS, and VARIATION.

Mr. Cavallo is of opinion, that the magnetism of the earth arises from the magnetism of all the magnetic sub-

MAGNETISM.

stances therein contained, and intermixed with other bodies; that the magnetic poles of the earth may be considered as the centres of the polarities of all the particular aggregates of the magnetic substances; and that these principal poles must change place, relatively to the surface of the earth, according as the particular aggregates of magnetic substances within the earth are in some manner or other altered, so as to have their power diminished, increased, approached, or removed from the principal poles.

Although no regularity has been established with respect to the variation of the needle, yet as the different situation of the magnetic poles within the earth occasions a great variety of appearances, and as the right understanding of these varieties may be of great use to those who wish to investigate this intricate subject, the development of which will be of vast use to mankind; we shall here subjoin the principal cases, as they are drawn up by Mr. Lorimer, which seem to be possible, relating to the position of the magnetic poles; conceiving, agreeably to the most natural and most generally received supposition, that they are two, and that they lie on the surface of the earth. These cases are no more than four, *viz.*

Case 1.—If the magnetic poles of the earth had coincided with the true poles thereof, there could have been no declination or variation of the mariner's compass in any part of the world, that is, if the earth be uniformly magnetical; for, in that case, the needle, in pointing to the magnetic poles, would always have pointed to the true poles also; this needle would therefore be necessarily directed along the course of the meridian, or, in other words, it would have no declination or variation either to the east or west thereof.

Case 2.—If the magnetic poles were situated in the same meridian, and in opposite parallels; upon that meridian which passes through the magnetic and true poles, from the one of the magnetic poles to the other, and upon the opposite meridian all along, there could be no declination, for the reason mentioned in the former case. Likewise, upon the equator, there would be no declination; for though if one of the magnetic poles were only to act upon the needle, in passing along the equator to the distance of 90 degrees in longitude east or west, the declination would increase, so that at 90 degrees distance from the line of no declination it would be equal to the angle contained between the magnetic and true poles; yet, as the other magnetic pole, in this case, is always within the same distance of the needle, it will act upon the opposite end of it with equal force, and consequently, will keep it parallel to itself all round the equator. But in going from the equator north or south, the declination would increase so as to be 180 degrees on the little arches or spaces of the meridian contained between the true and the magnetic poles, which is the greatest possible declination in all cases whatsoever. It must be farther observed on this case, that the lines of no declination, including those arches of 180°, form two great circles of the globe along the meridian and the equator, crossing one another at right angles, and dividing the surface of this globe into four quarters, two in each hemisphere; the one hemisphere having west declination in the north, and east declination in the south half thereof, and in the opposite hemisphere it would be just the reverse; so that each of the arches or semicircles of no declination would have east declination on the one side of them, and west declination on the other. The small arches of 180° declination, which are between the true and magnetic poles, may be reckoned in all cases as a part of the lines of no declination; for there indeed the needle conforms itself to the meridian as well as in the other parts of the circle, though its ends are reversed. In short,

as all the lines of declination do coincide and terminate in the magnetic and true poles, so these arches of 180° are a kind of limit, making with each of those lines, as in the present case, a curve line or figure returning into itself; which figures, from 180° between the poles, to 0° declination upon the equator, do each of them include a space larger than the other, till at last they fill up the whole quarter of the surface of the globe, and conform themselves, as nearly as possible, to the shape and figure thereof.

As a variety of this case, it may be added, that the magnetic poles may be situated in the same meridian, but in parallels which are not opposite. In that case, the only alteration which could happen is, that in the hemisphere in which the magnetic and true poles are nearest to each other, the figures formed by the lines of declination become smaller, and the corresponding figures in the opposite hemisphere, larger. The line of no declination, which, in this case, represents the equator, would also be proportionably nearer to those poles which are nearest to one another.

Case 3.—If the magnetic poles were situated in opposite meridians, and in opposite parallels; upon those meridians which pass through the magnetic and true poles there could be no declinations, for the reasons mentioned in the former cases. But upon the equator, eastward or westward, to the distance of 90° in longitude, the declination would actually increase, so as there to be equal to the angle which measures the distance between the true and the magnetic poles; and from thence it would, in the same manner, decrease for the other 90° to the opposite meridian. The declination lines of 10°, 20°, &c. as far as the greatest declination upon the equator, in this case, become arches or curves, which conform themselves, as nearly as may be, to the course and direction of the lines of no declination, and are called lines of the first order. But the lines of the greatest equatorial declination cross one another at the distance of 90° in longitude from the meridian or circle of no declination, something in form like the letter X, or like two Gothic arches joined at the vertex. They are called lines of the second order, and may very properly be considered as the boundary between the lines of the first and third order, as the lines of no declination are always boundaries between the lines of east and west declination. In this case, those lines of no declination, including the arches of 180°, form only one great circle along the meridian, dividing the surface of this globe into two hemispheres, in the one of which there is east declination, and in the other west declination.

From the greatest equatorial declination to the arches of 180°, the declination lines of the third order are curves returning into themselves, and in shape nearly resembling parabolas erected upon those arches of 180°.

As a variety of this case, it may be added, that if the magnetic poles were situated in opposite meridians, but in parallels which are not opposite, then, in that hemisphere in which the true and the magnetic poles approached nearest to one another, the figure formed by the lines of declination would be smaller, and in the opposite hemisphere the corresponding figures would be larger in proportion.

Case 4.—This case is a very extensive one, *viz.* when the magnetic poles are situated neither in the same nor in opposite meridians; and this seems to have been the real position of those poles ever since any observations of the declination of the magnetic needle have been made.

In this case, then, the lines of no declination cannot be either in the direction of a meridian or along the equator, as in the former case, but in a kind of curves, which are variously inclined to both; and they divide the surface of the globe into two parts, but these parts are not hemispheres,

MAGNETISM.

spheres, as in the last case, for they may be of a very different extent. If the magnetic poles be situated in meridians nearly opposite, the curvature of those lines will not be so great, that is, they become more like to Case 3. But as the magnetic poles approach nearer to the same meridian, the curvature of the lines of no declination becomes greater, till they almost touch one another, something in form like the figure of the number 8, and at last they complete the two great circles, as in Case 2. The lines of the second order, which correspond to the greatest equatorial declination, if the magnetic poles be situated in meridians nearly opposite, have a declination nearly equal to the angle formed between the magnetic and true poles, as in Case 3; but as the magnetic poles approach towards the same meridian, this declination decreases, till at last it entirely vanishes, as in Case 2. The other declination lines in this case are so similar to the former, that they require only to be referred to it. Lastly, it must be observed, that whether the magnetic poles be situated in opposite parallels or not, makes as little difference in this as in the former case.

Hitherto the magnetic poles have been considered to lie on the surface of the globe; but if we attentively consider the situation which they may more likely have, it will appear, that in all probability they are not situated near the surface of this globe, but at some depth below it; at least this must be the case with the south pole; for, since the water of the sea is incapable of magnetism, and the southern hemisphere, especially about the south pole, contains a vast deal more sea than land; it is plain that the south magnetic pole must be situated at least near the bottom of the sea; in consequence of which, the variation of the needle in that hemisphere must be different from what it would be if the magnetic pole were situated on the surface of the terraqueous globe. The same may be observed with respect to the situation of the north magnetic pole. Besides this, we must also consider the irregularities arising from the unequal and irregular situation of land and sea; it being natural to conceive, that large tracts of land on one side of the magnetic needle will draw it away from the real meridian, whereas a large ocean can produce no such effect. This, however, is subject to a great deal of variety, arising from the nature of the land, the depth of the sea, the nature of the ground at the bottom of the sea, &c. It appears, therefore, that a great many causes combine to act upon the magnetic needle, occasioning it to decline from the true meridian, and that it is almost impossible to form a useful theory upon it.

MAGNETISM, Theory of. As for the causes of magnetism, or the manner in which attraction, repulsion, and other magnetic phenomena are produced, we have yet no hypothesis, that will satisfactorily account for them. Plutarch tells us, the magnet attracts iron, by emitting some spiritual effluvia, whereby the contiguous air being opened and driven on either side, does again drive that contiguous to it; and thus the action being communicated round, the iron is thereby protruded; but this is contradicted by the equally vigorous action of the load-stone in vacuo, and in the open air. Others of the ancients ascribe the action of a magnet to a soul that animates it; and others to an unknown sympathy between the effluvia of the iron and those of the magnet.

An opinion, that has much prevailed among the moderns is that of Des Cartes, maintained by Malebranche, Rohault, Regis, &c. and even admitted and confirmed by Mr. Boyle, &c. In this it is supposed, that there is continually flowing, from the poles of the world, a subtle, impalpable, and invisible matter, channelled or striated;

which matter, circulating round the earth, in the planes of the meridians, re-enters at the pole, opposite to that from which it issued, and passes again through the poles parallel to its axis: that the magnet has two poles answerable to those of the earth; and that out of these there issues a matter like that just mentioned; and that this matter, entering at one of the poles, gives the impulse, whereby iron tends to the magnet, and produces what we call attraction. Now, besides the magnetical matter re-entering the poles of the magnet, there is always a certain quantity thereof circulating round the magnet, composing a kind of vortex about it. The space wherein this matter moves, is the sphere of activity of the magnet, within which its attractive faculty is confined.

Dr. Gilbert, in his work "De Magnete," folio, printed 1600, concludes, from some experiments which he made, that the needle is not attracted by the magnet, but turned into its position, by what he calls a disponent virtue; which he supposed to surround the stone, somewhat in form of an atmosphere.

As to its directive faculty, or the inclination of a needle touched with it to the poles of the world, and its dip to a point beneath the horizon, they follow from the same principle; since, were the magnet or needle to have any other situation, the magnetic matter would strike on its other surface in vain; and, not being able to get admission, would, by degrees, change its situation, till such time as its pores corresponded to the course of the magnetical matter; which situation having once acquired, it would cease to move, the magnetical matter then ceasing to disturb it.

The form or essence of a magnet, therefore, is supposed to consist in its being perforated by an infinite number of parallel pores; some of which are disposed to admit the striated matter from the north pole of the world, others that of the south: hence the north and south poles of the magnet.

Mr. Hartfoeker maintains, that the magnet is no more than a common stone, full of an infinite number of hollow prisms; which, by the diurnal motion of the earth, are ranged parallel to each other, and nearly parallel to the axis of the earth. These prisms have their cavities filled with an extremely subtle matter, which, by the diurnal motion of the earth, is passed from prism to prism; thus making a circulation, and returning into the prisms, where it first began. From these principles he deduces all the phenomena of the magnet; and M. Andry does the same, from the doctrine of alkali and acid.

As to the directive power of the magnet, Mr. Whiston inclines to think it mechanical; and ascribes it to magnetic effluvia circulating continually round the load-stone; of which circulations, he thinks, there are evident indications in magnetic experiments; as Mr. Boyle thinks there are of the magnetism, or magnetic effluvia of the earth; though these effluvia are never yet rendered sensible, as electric effluvia began to be in his time. But the attractive power Mr. Whiston thinks entirely immechanical, as the power of gravity is; not being able to devise any such motion of a subtle fluid belonging to the load-stone, as will account for the attractive power in the selfduplicate proportion of the distances reciprocally; though if he could, yet would that be no more than to remove the immediate power of the Supreme Being one step farther; the last resort of all mechanical principles whatever being in the immechanical power and efficacy of the Deity.

Dr. Knight deduces from several experiments the following propositions, which he offers, not so much to explain the nature of the cause of magnetism, as the manner in which it acts: the magnetic matter of a load-stone, he says,

moves in a stream from one pole to the other internally, and is then carried back in a curve line externally, till it arrive again at the pole where it first entered, to be again admitted; the immediate cause why two or more magnetic bodies attract each other, is the flux of one and the same stream of magnetical matter through them: and the immediate cause of magnetic repulsion is the confluent and accumulation of the magnetic matter. His opinion was, that this earth had originally received its magnetism, or rather that its magnetical powers had been brought into action, by a shock, which entered at about the southern, and passed out at the northern tropic. This, according to his statement, was the course of the magnetic fluid, and he supposed, that the magnetic poles were at first diametrically opposite to each other. But if this was the case at first, we are led to conclude from Mr. Canton's doctrine, that they would not long have continued so; for, on account of the intense heat of the sun in the torrid zone, according to the principles stated under the article DECLINATION, the north pole must soon have retired to the north-eastward, and the south pole to the south-eastward. (Phil. Transf. vol. xlv. p. 665, &c.) Mr. Michell rejects the notion of a subtle fluid; but though he proposed to publish a theory of magnetism established by experiments, no such theory has appeared. Signior Beccaria, from observing that a sudden stroke of lightning gives polarity to magnets, conjectures, that a regular and constant circulation of the whole mass of the electric fluid from north to south may be the original cause of magnetism in general. This current he would not suppose to arise from one source, but from several, in the northern hemisphere of the earth: the aberration of the common centre of all the currents from the north point, may be the cause of the variation of the needle, the period of this declination of the centre of the currents may be the period of the variation, and the obliquity with which the currents strike into the earth may be the cause of the dipping of the needle, and also why bars of iron more easily receive the magnetic virtue in one particular direction. *Lettre dell' Eletticismo*, p. 269, or Priestley's *Hist. Elec.* vol. i. p. 409, &c.

Similar to the last hypothesis is that proposed by the ingenious *Æpinus*, (*Tentamen Theoriæ Electricitatis et Magnetismi*, cap. i. § 3.) which, though labouring under several objections, seems however to be the most plausible.

From the analogy of the established or more common hypothesis of electricity, which goes under the name of Dr. Franklin's, Mr. *Æpinus* is led to imagine, that there exists a fluid productive of all the magnetic phenomena, and consequently to be called the *magnetic fluid*; that this fluid is so very subtle as to penetrate the pores of all bodies; and that it is of an elastic nature, *viz.* that its particles are repulsive of each other.

He farther supposes, that there is a mutual attraction between the magnetic fluid and iron, or other ferruginous bodies; but that all other substances have no action on this fluid; they neither attracting nor repelling each other.

He then observes, that there is a great deal of resemblance between ferruginous bodies and electrics, or non-conductors of electricity; for the magnetic fluid passes with difficulty through the pores of the former, as well as the electric fluid passes with difficulty through the pores of the latter. However, there is not a body that has any action on the magnetic fluid, and is, at the same time, analogous to non-electrics; for instance, there is no body, the particles of which attract the magnetic fluid; and yet this fluid can pervade its pores without any obstruction. In iron, in-

deed, a kind of gradation of this sort seems to take place; for, the softer the iron is, the more freely does the magnetic fluid pervade its pores; and, on the contrary, the harder it is, the greater opposition it offers to the free passage of that fluid; so that the iron, when soft, seems to be more analogous to non-electrics than when hard.

According to this hypothesis, iron, and all ferruginous substances, contain a quantity of magnetic fluid, which is equally dispersed through their substance, when those bodies are not magnetic; in which state they shew no attraction nor repulsion against each other, because the repulsion between the particles of the magnetic fluid is balanced by the attraction between the matter of those bodies and the said fluid, in which case those bodies are said to be in a natural state; but, when in a ferruginous body, the quantity of magnetic fluid belonging to it is driven to one end, then the body becomes magnetic, one extremity of it being now overcharged with magnetic fluid, and the other extremity undercharged. Bodies thus constituted, *viz.* rendered magnetic, exert a repulsion between their overcharged extremities, in virtue of the repulsion between the particles of that excess of magnetic fluid; which is more than overbalanced by the attraction of their matter. There is an attraction exerted between the overcharged extremity of one magnetic body, and the undercharged extremity of the other, on account of the attraction between that fluid and the matter of the body; but to explain the repulsion, which takes place between their undercharged extremities, we must either imagine that the matter of ferruginous bodies, which deprived of its magnetic fluid, must be repulsive of its own particles, or that the undercharged extremities appear to repel each other, only because either of them attracts the opposite overcharged extremities; both which suppositions are embarrassed with difficulties.

A ferruginous body, therefore, is rendered magnetic by having the equable diffusion of magnetic fluid throughout its substance disturbed, so as to have an overplus of it in one or more parts, and a deficiency of it in one or more other parts; and it remains magnetic as long as its impermeability prevents the restoration of the balance between the overcharged and undercharged parts. Moreover, the piece of iron is rendered magnetic by the vicinity of a magnet; because, when the overcharged part or pole of the magnet is presented to it, the overplus of magnetic fluid in that pole repels the magnetic fluid away from the nearest extremity of the iron, which, therefore, becomes undercharged, or possessed of the contrary polarity, to the most remote part of the iron, which consequently becomes overcharged, or possessed of the same polarity as the presented pole of the magnet. When the piece of iron is rendered magnetic by presenting to it the undercharged extremity or pole of the magnet, then the part of the iron which is nearest to it, becomes overcharged, &c. because that part of the magnet, being deprived of its magnetic fluid, attracts the magnetic fluid of the iron to that extremity of the iron which lies nearest to itself.

In consequence of which it appears, that, in order to give magnetism to a body, as a piece of steel, the strength of the magnet employed must be such as to overcome the resistance, which the substance of the steel makes against the free passage of the magnetic fluid; hence, a piece of soft steel is rendered magnetic more easily than a hard one; hence, a stronger magnet will render magnetic such ferruginous bodies, as other smaller magnets have no power upon.

The action of two magnets upon each other is likewise easily explained by this hypothesis. When two equal magnets

nets oppose their contrary poles to each other, they thereby preserve and strengthen their power; but when the homologous poles of two magnets are placed near, then, if the strength and quality of those magnets be equal, they will only diminish each other's magnetic power; but, if they be unequal in power or other quality, as the hardness, shape, &c. then the weakest will have its power diminished, destroyed, or changed, in proportion to its softness, weakness of magnetism, and other circumstances, which will easily occur to the intelligent reader.

Our venerable countryman, Mr. Cavendish, had invented a similar theory, and had entered in many respects more minutely into the detail of its consequences without being acquainted with the above-cited work of Æpinus; although the publication of his paper on the subject was 12 years later. Lambert, Meyer, Coulomb, and Robison have also pursued inquiries of a similar nature, both theoretically and experimentally, with great success. See Young's *Philosophy*, vol. i. lect. 55.

MAGNETISM, *Laws of*. See MAGNET, *supra*.

MAGNETISM and Electricity, *Analogy between*. The well-known property of amber, by which, after being rubbed, it attracts small bodies, was, in an early period of the science of electricity, described under the appellation of the magnetism of amber; so that these two powers, the electrical and the magnetic, were considered as the same, or at least not sufficiently distinguished. At a later period these two powers have been regarded as quite distinct from each other, but in several respects exhibiting a mutual resemblance. We shall, therefore, here state some particulars in which they resemble one another, and others in which they differ. The power denominated by philosophers *electricity* (see that article) is of two sorts, *viz.* the *positive*, and the *negative* electricity. In the science of electricity, it is an invariable law, that bodies possessed of the same sort of electricity repel each other, whereas those which are possessed of different electricities attract each other.

Thus, in magnetics, there is a north and a south pole; those parts of magnetic bodies which are possessed of the same polarity, repel each other; but those which are possessed of different polarities attract each other.

In electricity, whenever a body in a natural state is brought within the sphere of action of an electrified body, it becomes itself electrified, and possessed of the contrary electricity, after which an attraction takes place; so that in truth there is no electric attraction but between bodies possessed of different electricities: for instance, if a piece of paper be brought sufficiently near a glass tube, electrified positively, the paper will acquire the negative electricity, and will then be attracted by the tube; but if the paper be so circumstanced as not to have it in its power to acquire the negative electricity, then no attraction will take place.

Thus, a ferruginous substance, which is brought within the sphere of action of a magnet, cannot be attracted by either pole of the magnet, unless it acquires first a contrary polarity.

One sort of electricity cannot be produced by itself, but is always accompanied by the other; thus, if a glass tube be electrified positively on its external surface, a negative electricity must exist, either on its internal surface, or on the air contiguous to the tube.

In the same manner, the two magnetic poles are always together; nor was there a piece of ferruginous substance ever produced, which had one polarity, and not the other.

The electric virtue can be retained and confined by certain bodies, like glass, amber, resins, and others, called *electrics*;

but it easily pervades other substances, called *conductors*, or *non-electrics*.

The magnetic virtue is retained by ferruginous substances, especially those of a hard nature, like hard steel, and the magnet: but it pervades easily, and without the least perceivable impediment, all other sorts of substances.

On the other hand, the magnetic power differs from the electric, first, in its not affecting our senses with any light, smell, taste, or noise; whereas, the electric spark, shock, smell, and taste, are known to every one conversant in electric experiments. Secondly, magnetism attracts only iron, or those bodies which contain that metal in some state or other; whereas, the electric power attracts bodies of every sort. Thirdly, the electric virtue resides on the surface of electrified bodies, whereas the magnetic is quite internal. Lastly, a magnet loses nothing of its power by magnetising other substances; but an electrified body loses part of its electricity by electrifying other substances. Here, however, must be remarked, that an electrified body loses part of its power, when in electrifying another body touches it, and that body acquires then the same sort of electricity; but when that other body is electrified by being only brought within the sphere of action of the former, in which case it acquires the contrary electricity, then the former body loses nothing of its power; for instance, suppose that a body, A, possesses a certain quantity of positive electricity, and that another body B, in a natural state, be gradually brought near A; then the body B, when it comes within a certain distance of the electrified body A, acquires a negative electricity, which negative electricity takes away nothing of the power of the body A; but if the two bodies come very near, so as to touch, or as that the electricity of the body, A, may leap from it to the other, then the body, B, will become electrified positively, and A loses thereby part of its power. Indeed, if it be duly considered, this last case does not seem ever to take place with magnetism; for bodies appear to be rendered magnetic merely by the action of their spheres of activity, or by that power which enables magnets to act at some distance from their own bodies; and therefore we may justly say, that electrified and magnetic bodies agree in this, *viz.* that they lose nothing of their power, when other bodies are electrified or rendered magnetic in virtue of their spheres of activity.

When the *aurora borealis*, which has been thought to be an electrical phenomenon, forms a luminous arch towards the northern part of the horizon, the most elevated part, or middle of that arch, is generally in the magnetic meridian.

Several other points of analogy, or of difference between magnetism and electricity, will, perhaps, occur to those persons who examine both subjects; but if they be attentively considered, we think they will be found to be comprehended in those which have been enumerated above. Cavallo's Magnetism, and Priestley's Electricity, *ubi supra*.

MAGNETISM, *Animal*, an appellation given by some designing or self-deceived operators upon the credulity and pures of mankind, to certain practices, by which, under the pretence of curing diseases, various effects were produced on the animal economy, such as faintings, partial and even general convulsions, &c. These practices were principally carried on in France, by a person of the name of Mesmer, and his disciples, and were believed to influence the human body through the medium of the magnetic principle. In consequence, however, of the appointment of a committee of philosophers for the investigation of the matter by the French king, the true nature of the operation was proved, in the most unequivocal manner, and the effects of it traced,

by the clearest experiments, solely to the mind or *imagination* of the persons *magnetised*. An ample detail of this able investigation, as well as of several other facts and practices referrible to the same source, will be found under the article **IMAGINATION**.

MAGNETISM is also used, by some *Chemists*, to signify a certain virtue, whereby one thing becomes affected at the same time with another, either in the same or in a different manner. This amounts to the same with what they otherwise call *sympathy*.

It has been observed, that much confusion in the science of magnetism has been occasioned by the application of the term *magnetism* to other things which had no relation to it. Thus, the chemical affinity between metals has been called the magnetism of metals by some old authors. The vibration occasioned by the sound of musical strings or pipes upon others which were tuned in concord with them has been also called the magnetism of music. Some writers also speak of the magnetism of astronomy, the magnetism of water, &c.

MAGNICOURT, in *Geography*, a town of France, in the department of the straits of Calais, and chief place of a canton, in the district of St. Pol; two leagues S.E. of St. Pol.

MAGNIFYING, among *Philosophers*, is chiefly used in speaking of microscopes, which are said to magnify objects, that is, to make them appear bigger than they really are, though in reality they do not, nor can, magnify any object, but only shew it nearer, and discover more of its parts than before were taken notice of.

The magnifying power of dense mediums of certain figures was known to the ancients, though they were far from understanding the cause of this effect. Seneca says, that small and obscure letters appear larger and brighter through a glass globe filled with water; and he absurdly accounts for it by saying, that the eye slides in the water, and cannot lay hold of its object. *Nat. Quest. lib. i. c. 6.*

Alexander Aphrodisiensis, the great commentator upon Aristotle, who flourished near two centuries after Seneca, says, that the reason why apples appear large when they are immersed in water is, that the water which is contiguous to any body is affected with the same quality and colour; so that the eye is deceived in imagining the body itself to be larger. But the first distinct account we have of the magnifying power of glasses is in the writings of Alhazen, who flourished in the twelfth century; and he was preceded by our countryman Roger Bacon, who, in his *Opus Majus*, demonstrates, that if a transparent body, interposed between the eye and an object, be convex towards the eye, the object will appear magnified; nor is it improbable, that from the observations of Alhazen and Bacon the construction of spectacles was derived. See **SPECTACLES**.

MAGNIFYING Glass, in *Optics*, denotes a little spherical convex lens; which, in transmitting the rays of light, affects them, so as that the parallel ones become converging, and those which were diverging become parallel; by means whereof, objects viewed through them appear larger than when viewed by the naked eye. See **MICROSCOPE**.

MAGNIN, in *Geography*, a town of Egypt, on the left bank of the Nile; 12 miles S. of Shabur.

MAGNISA, anciently **MAGNESIA**, a town of Asiatic Turkey, in the province of Natolia, situated near a mountain, whose top is always covered with snow. The town is large and populous, but has few Christians; 20 leagues N.N.E. of Smyrna. N. lat. 38° 44'. E. long. 27° 18'.

MAGNISI DEGLI, a peninsula of Sicily, on the E. coast, in the valley of Noto; six miles N. of Siracusa or

Syracuse; formerly the peninsula of Tapfus. Opposite to this peninsula are the ruins of a monument, said to have been erected in memory of the victory of Marcellus.

MAGNISSA, in *Mineralogy*, a name given by some of the ancients to the white pyrites, called by others *leucolithos* and *argyrolithos*. See **MARCASITE**.

MAGNITUDE, any thing that has parts without (or *extra* to) parts connected together by some common term.

Magnitude is any thing locally extended, or continued; or that has several dimensions.

The origin of all magnitude is a point, which, though void of parts itself, yet its flux forms a line, the flux of that a surface, and of that a body.

Magnitude amounts to much the same with what is otherwise called *quantity*.

MAGNITUDE, *Geometrical*, may be usually considered as generated or produced by motion. Thus lines may be conceived as generated by the motion of points; surfaces, by the motion of lines; solids, by the motion of surfaces; angles may be supposed to be generated by the rotation of their sides.

Geometrical magnitude is always understood to consist of parts; and to have no parts, or to have no magnitude, are considered as equivalent in this science. There is, however, no necessity for considering magnitude as made up of an infinite number of small parts; it is sufficient that no quantity can be supposed to be so small, but it may be conceived to be farther diminished; and it is obvious, that we are not to estimate the number of parts that may be conceived in a given magnitude, by those which in particular determinate circumstances may be actually perceived in it by sense, since a greater number of parts become sensible, by varying the circumstances in which it is perceived. See **Maclaurin's Fluxions**, art. 290, &c.

Many of late have supposed geometrical magnitude to be composed of infinitely small parts, and infinite in number; and hence have raised many paradoxes and mysteries in a science in which there ought to be none. Nay, infinitely small parts of infinitely small parts, &c. *ad infinitum*, have been introduced without the least necessity. See **Maclaurin's Fluxions**, in the Introduction, where he makes several remarks on Monsieur de Fontenelle's *Geometrie de l'Infini*. See **EXTENSION**.

MAGNITUDE, *Literal*, denotes a magnitude expressed by letters.

MAGNITUDE, *Numerical*, is that expressed by numbers.

MAGNITUDE, *Broken*, denotes a fraction.

MAGNITUDE, *Complex*, is that formed by multiplication.

MAGNITUDE, *Incommensurable*, is that which has no proportion to unity.

MAGNITUDE, *Apparent*, of a body, in *Optics*, is that measured by the optic or visual angle intercepted between rays drawn from its extremes to the centre of the pupil of the eye. It is one of the fundamental maxims in this science, that whatever things are seen under the same or equal angles, appear equal; and *vice versa*.

The apparent magnitudes of an object at different distances, are in a ratio less than that of their distances reciprocally.

The apparent magnitudes of the two great luminaries, the sun and moon, at rising and setting, are phenomena that have extremely embarrassed the modern philosophers. According to the ordinary laws of vision they should appear the least when nearest the horizon, as being then farthest distant from the eye; and yet we find the contrary to be true in fact.

Thus it is well known, that the mean apparent magnitude
of

MAGNITUDE.

of the moon is $30' 30''$, in round numbers $30'$, at a full moon in the midst of winter, and when she is in the meridian, and at her greatest northern latitude, and consequently at her utmost elevation above our horizon: it is also as well known that when she is in this situation, being looked upon by the naked eye, she appears to be, accommodating her magnitude to our sensible measures, about a foot broad. But when she is looked upon as she rises, she appears to be three or four feet broad, and yet if we take her diameter with an instrument, both in the one situation and the other, we shall find that she is only $30'$.

Ptolemy, in his *Almagest*, lib. i. cap. 3, has ascribed this appearance to a refraction of the rays by vapours, which actually enlarge the angle under which the moon appears; just as the angle is enlarged by which an object is seen placed under water; and his commentator Theon explains distinctly how the dilatation of the angle in the object immersed in water is caused. But it was afterwards discovered, that there is no alteration in the angle: upon which another solution was started by the Arab Alhazen; and followed and improved by Vitellio, Kepler, Peckham, Roger Bacon, and others. According to Alhazen, the sight apprehends the surface of the heavens as flat, and judges of the stars as it would of ordinary visible objects extended upon a wide plain; the eye sees them under equal angles, but at the same time perceives a difference in their distances, and (on account of the semidiameter of the earth, which is interposed in one case and not in the other) it is hence induced to judge those which appear more remote to be greater. Some farther improvement was made in this explanation by Mr. Hobbs, though he fell into some mistakes in his application of geometry to this subject. For he observes, that this deception operates gradually from the zenith to the horizon; and that if the apparent arch of the sky be divided into any number of equal parts, those parts, in descending towards the horizon, will gradually subtend a less and less angle; and he was the first who expressly considered the vaulted appearance of the sky as a real portion of a circle. Des Cartes, and from him Dr. Wallis, and most other authors, account for the appearance of a different distance under the same angle, from the long series of objects interposed between the eye and the extremity of the sensible horizon; which makes us imagine it more remote than when in the meridian, where the eye sees nothing in the way between the object and itself. This idea of a great distance makes us imagine the luminary the bigger; for any object being seen under any certain angle, and believed at the same time very remote, we naturally judge it must be very large, to appear under such an angle, at such a distance. And thus a pure judgment of the mind makes us see the sun, or moon, bigger in the horizon than in the meridian; notwithstanding their images painted on the retina are less in the former situation than the latter.

James Gregory, *Geom. Par. Univers.* p. 141, subscribes to this opinion: Father Malebranche also, in the first book of his "*Récherches de la Vérité*," printed in 1673, has explained this phenomenon almost in the expression of Des Cartes: and Huygens, in his treatise on the Parhelia, translated by Dr. Smith, *Optics*, art. 536, has approved, and very clearly illustrated the received opinion. The cause of this fallacy, says he, in short is this; that we think the sun or any thing else in the heavens to be remoter from us, when it is near the horizon, than when it approaches towards the vertex, because we imagine every thing in the air that appears near the vertex to be no farther from us than the clouds that fly over our heads; whereas, on the other hand, we are used to observe a large extent of

land lying between us and the objects near the horizon, at the farther end of which the convexity of the sky begins to appear; which, therefore, with the objects that appear in it, is usually imagined to be much farther from us. Now when two objects of equal magnitudes appear under the same angle, we always judge that object to be larger which we think is remoter. And this is the true cause of the deception we have been speaking of. It is a wonder that an hypothesis so rational as this should ever lose its credit, after having been maintained by writers of reputation, and for a great number of years. But it was generally imagined, that the actual perception of those objects which divide the space that is intercepted betwixt the eye and the horizon was necessary, in order to its suggesting the idea of its extraordinary distance: and thus philosophers were led to form much more objectionable solutions of the phenomenon. Accordingly Gassendus was of opinion, that the pupil of the eye, which is always more open as the place is more dark; being more so in the morning and evening than at other times, because the earth is covered with gross vapours; and besides, being obliged to pass through a longer column or series of vapours to reach the horizon; the image of the luminary enters the eye at a greater angle, and is really painted there larger at the former times than the latter. In answer to which it may be said, that notwithstanding this dilatation of the pupil, occasioned by the obscurity, if the moon be viewed through a little pin-hole made in a paper, she appears less when in the horizon than in the meridian. Nor can any thing be more absurd than the position of Gassendus, who asserts, that a dilated pupil magnifies an object for the same reason as a convex glass does.

F. Gouye advances another hypothesis, which is, that when the luminaries are in the horizon, the neighbourhood of the earth, and the gross vapours wherewith they then appear enveloped, have the same effect with regard to us, as a wall, or other dense body, placed behind a column; which, in that case, appears bigger than when insulate, and encompassed on all sides with an illumined air. Farther, it is observed, that a column, when fluted, appears bigger than before, when it was plain; the flutes being so many particular objects, which, by their multitude, occasion the mind to imagine the whole object, whereof they are composed, of a larger extent. The same thing may be said of the several objects seen towards the horizon, to which the sun or moon correspond at their rising and setting. And hence it is, that they appear larger still, when they rise or set between trees; the narrow, yet distinct, intervals whereof have the same effect with regard to the apparent diameter of the luminary, as a greater number of flutes with regard to the shaft of a column.

Bishop Berkeley supposed, that the moon appears larger near the horizon, because her appearance is then fainter, and her beams affect the eye less; but this hypothesis is refuted by Dr. Smith. Mr. Robins has recited some other opinions on this subject, *Math. Tracts*, vol. ii. p. 242. The commonly received opinion has been disputed not only by F. Gouye, who observes, *Acad. Par.* 1700, p. 11, that the horizontal moon appears equally large across the sea, where there are no objects to produce the effect ascribed to them; but also by Mr. Molyneux, who says, *Phil. Trans.* abr. vol. i. p. 221, that if this hypothesis be true, we may at any time increase the apparent magnitude of the moon, even in the meridian; for, in order to divide the space between it and the eye, we need only to look at it behind a cluster of chimneys, the ridge of a hill, or the top of a house. He also makes the same observation with F. Gouye, above-mentioned, and farther observes,

erves, that when the height of all the intermediate objects is cut off, by looking through a tube, the imagination is not helped, the moon being still conceived to be as large as before. However, Mr. Molyneux advances no hypothesis of his own. Dr. Defaguliers has well illustrated the doctrine of the horizontal moon, *Phil. Trans. abr.* vol. viii. p. 130, upon the supposition of our imagining the visible heavens to be only a small portion of a spherical surface, and consequently supposing the moon to be farther from us in the horizon than near the zenith, and by several ingenious contrivances he demonstrated how liable we are to such deceptions. But the most complete illustration of this curious subject is given us by Dr. Smith. The cavity of the heavens, he says, appears to the eye, which is the only judge of an apparent figure, to be a less portion of a spherical surface than a hemisphere. In other words, the centre of the concavity is much below the eye, and by taking a medium among several observations, he found that the apparent distance of its parts at the horizon was generally between three or four times greater than the apparent distance of its parts over head. This he determined by measuring the actual height of some of the heavenly bodies, when, to his eye, they seemed to be half way between the horizon and the zenith. In this case their real altitude was only twenty-three degrees. When the sun was but 30 high, the upper arch always appeared less than the under, and he thought that it was always greater when the sun was about 18 or 20° high. Mr. Robins, in his *Traacts*, vol. ii. p. 245. shews how to determine the apparent concavity of the sky in a more accurate and geometrical manner; by which it appears, that if the altitude of any of the heavenly bodies be 20 at the time when it seems to be half way between the horizon and the zenith, the horizontal distance will be hardly less than four times the perpendicular distance; but if that altitude be 28, it will be little more than two and a half. Dr. Smith having determined the apparent figure of the sky, is able to give a satisfactory explanation of the phenomenon of the horizontal moon, and other similar appearances in the heavens. For supposing the arc *A B C*, (*Plate X. Optics*, *fig. 4.*) to represent that apparent concavity, he found that the diameter of the sun and moon would seem to be greater in the horizon than at any proposed altitude, measured by the angle *A O B*, in the proportion of its apparent distances *O A*, *O B*. The numbers that express these proportions he reduced into the following table, answering to the corresponding altitudes of the sun or moon, which are also exactly represented to the eye in the figure, in which the figures of the moon, placed in the quadrantal arc *F G*, described about the centre *O*, are all equal to each other, and represent the body of the moon in the heights here noted, and the unequal moons in the concavity *A B C* are terminated by the visual rays that come from the circumference of the real moon, at

The sun or moon's altitude in degrees.	Apparent diameter or distances

90	30

those heights, to the eye, at *O*. The diameters of these unequal moons at *A* and *B* do, therefore, bear the same proportion to each other, as their apparent distances *O A*, *O B*; and they must appear in the same proportion that they really have in this concave, because we judge all objects in the heavens to be in this surface: so that the appearance to the eye is exactly the same, as if several moons were painted upon a real surface, *A B C*, in the proportions here assigned; in which

case we should certainly judge the real magnitudes of the larger paintings of the lower moon to be really larger, though the visible magnitudes of them all, answering to their equal images upon the retina, were exactly equal. For the same reason Dr. Smith observes, that all the objects and distances of stars in the heavens, as well as the sun and moon, must seem to be greater in the horizon than in higher situations; which is known to be the case. He also observes, that the apparent concave of the sky being less than an hemisphere, is the cause that the breadths of the colours in the inward and outward rainbows, and the interval between the bows appear least at the top, and greater at the bottom; and by an estimate of the apparent breadths of the inward rainbow, at two different heights, made by a friend, he determined the apparent concavity of the sky to be much the same as by the former methods. (See *HALO*.) This theory of the horizontal moon is also confirmed by the appearances of the tails of comets, which, whatever be their real figure, magnitude, and situation in absolute space, do always appear to be an arc of the concave sky; and in farther confirmation of it, he gives us Mr. Cotes's explanation of the optical appearance of a remarkable meteor seen in the year 1716. Besides the general cause above stated of the appearance of the horizontal moon, Dr. Smith acknowledges, that, at different times, the moon appears of different magnitudes even in the same horizon, and occasionally of an extraordinary large size. This, he is inclined to believe, is chiefly owing to an extraordinary largeness of her picture upon the retina, which, in the preceding general theory, was supposed to be invariable. This, he says, might best be examined by taking the diameter of the moon with a micrometer, or by noting the year and day of the month, together with the heights of the barometer and thermometer. For if it should appear, by many such observations, that the largest horizontal moons generally happen at her perigee, in the warmest summer evenings, the barometer being low, and the thermometer high; since these causes are independent of one another, and all conspire to enlarge the picture of the moon, we may reasonably conclude that these extraordinary moons are chiefly owing to the concurrence of these circumstances. But since the difference in the apparent magnitude of the moon is not increased $\frac{1}{8}$ th part of the whole in consequence of her being in her perigee, and the enlargement of the image in all the other cases here mentioned is very inconsiderable, it is probable that when the moon is imagined to be so much larger than usual, the imagination is farther imposed upon by some circumstances which have not been attended to. *Smith's Optics*, vol. i. p. 63, &c. *Remarks*, p. 53.

MAGNOL, PETER, in *Biography*, a celebrated botanist of Montpellier, was born in 1638. He was bred to physic, but, being a Protestant, could not take his degree there. He was therefore obliged to have recourse to some more sensible and more Christian university, where such exclusive laws were unknown. Such are not the reproach of popery only. A few years ago some members of the university of Oxford proposed that one of their honorary degrees should be conferred on Mr. Kirwan of Dublin; a proposal intended at least as much for their own honour as for his. But this was found to be impracticable, because forsooth that illustrious philosopher and distinguished character was a dissent! Wherever Magnol graduated, he practised physic at Montpellier for a long course of years, and at the same time very assiduously cultivated Botany, not only as an auxiliary to medicine, but with the most enlarged views to its advancement as a science of itself. He was beloved for his urbanity, and esteemed for his knowledge. Numerous botanists flocked at this time to Montpellier, that neighbourhood being

being famous for its vegetable riches; and these were all eager to enjoy the society, and to benefit by the guidance and instructions of so able a man. Hence the herborizations around Montpellier have become celebrated in so many books; and the situations of the *hortus Dei* at l'Esperou, the *Mons Ceti*, Castelnau, wood of Gramont, &c. have become classic spots. Among the pupils of Magnol were Fagon and the illustrious Tournefort, who regularly studied under him, and on many subsequent occasions gratefully acknowledged their obligations to him. He was not chosen public professor till long after the years 1679 and 1681, when Tournefort was at Montpellier. He had indeed been one of four persons, nominated, and recommended to the king for the vacant professorship, in 1667; but his religion was an insuperable obstacle to his appointment, as that of king Solomon himself would, in the same case, have been. This difficulty was removed, by his assuming the guise at least of Catholicism, before the year 1694, when he at length obtained the professorial chair.

In 1676, our author published at Lyons his first work, the *Botanicum Monspelienſe*, an octavo volume of 287 pages, with 22 plates. This same edition was republished at Montpellier in 1688, with a new title-page, and 20 pages of appendix. In this book Linnæus reckons that 1366 plants are enumerated; Haller says 1354; all found wild about Montpellier, and almost entirely gathered there by the author himself. Among these, very few of the class *Cryptogamia* are included, but some of them are now acknowledged varieties, and the last four of the appendix are exotics, inserted merely on account of their novelty. The arrangement of the work is alphabetical. The choice of the names is very select, and various criticisms or descriptions are subjoined, with the particular places of growth and medical virtues of each plant. The plates are rude, but original and characteristic. This is in fact one of the most original and authentic works of its kind, being to the Montpellier botanists what Ray's *Synopsis* is to those of Britain, the basis of all their knowledge. They are necessarily supposed to be able to give an account of every plant which it contains; but their ideas are by no means as yet correct respecting every one, and an accurate Linnæan *Flora Monspelienſis* is still a desideratum.

In 1689, Magnol published an octavo volume, entitled *Prodromus Historiæ Generalis Plantarum*, in which he undertook a scheme of natural arrangement. We have not seen this performance. Haller says the method is that of Ray, deduced from all the parts of a plant; and that the vegetable kingdom is disposed in 76 families, subdivided into genera. The author considers the flowers and fruits as of primary importance, but has recourse also to the roots and habit occasionally. Haller indicates a few mistakes. If they are the worst he could discover, the work must rank very high, even at the present day.

In 1697 appeared the *Hortus Regius Monspelienſis*, an 8vo. volume of 209 pages, with 21 elegant plates. This is an alphabetical catalogue of the garden, in which several new or rare species are described as well as figured. In their generic distribution the author conforms to Tournefort principally, and his preface shews how much he had contemplated this subject and its difficulties. When we consider that Magnol had had the care of the garden only three years previous to the publication of this rich catalogue, and that he found the collection in a very poor state, the book is an honourable monument of his industry as well as knowledge. The *Garidella*, *Saxifraga hirsuta* and *umbrosa*, *Lathyrus Nissolia*, and some others, here appear for the first time.

In 1708, Magnol was admitted a member of the *Académie*

des Sciences of Paris, in the place of his distinguished friend Tournefort, who died that year. He continued to prosecute his favourite studies, having prepared some observations upon the *Pinax* of Caspar Bauhin, which however he did not live to complete. He communicated to the *Académie des Sciences* some objections to the opinion of a circulating sap in vegetables, and some remarks on the importance of their *medulla* or pith. He also gave an account of an easy method of tinging the flowers of the *Tuberoſe* with a solution of some kind of lake.

Magnol died in 1715, at the age of 77. He left a son, named Anthony, who was professor of physic at Montpellier, but not of Botany. To this son we are indebted for the publication of the *Novus Character Plantarum*, on which the fame of Magnol as a systematic botanist chiefly rests. This posthumous work appeared in 1720, making a quarto volume, of 341 pages. The system therein taught is much celebrated by Linnæus, who in his *Classes Plantarum*, 375—403, gives a general view of it, expressing his wonder that so new and singular a system had not made more profelytes. It professes to be founded on the calyx; but that term is taken in a very wide, and, at this time of day, unauthorized sense; for it comprehends the pericarp as well as perianth, the former being denominated the internal calyx, the latter the external. It is necessary to observe that Linnæus, in the work above-mentioned, p. 376, sect. 2, α and β , by an erroneous transposition of the words *perianthium* and *pericarpium*, has rendered his account totally unintelligible.—According to this system, every plant is supposed to have either an external calyx (enfolding or sustaining the flower); or an internal one, which is the pericarp; or both. It is more natural than most early systems in its detail, but paradoxical in some of its primary characters. That sort of supposed external calyx, which merely sustains the flower, is often scarcely more than the receptacle of Linnæus, the real perianth being either passed over, or taken for a corolla. The classes devoted to trees and shrubs are, as Haller observes, very imperfect; but we can hardly subscribe to his decision, that the work ought, for the sake of its author, to have been consigned to oblivion. It is undoubtedly worthy the consideration of those who study natural affinities, and is not the less estimable for being hostile to the popular methods of its time, founded on the corolla; though that circumstance has probably contributed, more than any thing else, to its neglect. The corolla in this method of Magnol affords subordinate distinctions only, entering into none of those obscure and evanescent *minutæ*, on which some of the primary characters in the method of Tournefort depend.—Works of Magnol. MAGNOLIA, in *Botany*, a noble genus of trees or shrubs, named by Plumier in honour of Peter Magnol, Botanical Professor at Montpellier; see the last article. Linn. Gen. 278. Schreb. 373. Willd. Sp. Pl. v. 2. 1255. Mart. Mill. Dict. v. 3. Ait. Hort. Kew. ed. 2. v. 3. 329. Juss. 281. Plum. Gen. 38. t. 7. Lamarek Illustr. t. 490. Gartn. t. 70.—Class and order, *Polyandria Polygynia*. Nat. Ord. *Coadunata*, Linn. *Magnolia*, Juss.

Gen. Ch. *Cal.* Perianth inferior, of three ovate, equal, concave, petal like, deciduous leaves. *Cor.* of six, nine, or more oblong, concave, obtuse petals, narrower at the base. *Stam.* Filaments numerous, short, incurved, pointed, compressed and two-edged, inserted into the common receptacle of the pistils below the germens; anthers terminal, linear, of two cells, curling longitudinally at the inner side. *Pist.* Germens numerous, ovate-oblong, imbricated upon a cylindrical

MAGNOLIA.

dricul or ovate receptacle; styles recurved, very short; stigmas longitudinal, downy. *Peric.* Capsules numerous, sessile, crowded, coriaceous, compressed, wedge-shaped, of one cell and two valves bursting outwards, permanent. *Seeds* one or two in each cell, roundish-oblong, pulpy, coloured, at length hanging by a thread-like stalk, out of the capsule.

Eff. Ch. Calyx of three leaves. Petals six to twelve. Anthers bursting inwardly. Capsules of two valves, crowded into the form of a cone. Seeds pulpy, pendulous.

Obf. For the distinctions between this genus and *Liriodendrum*, see that article.

1. *M. grandiflora*. Laurel-leaved Magnolia. Andr. *Repos.* t. 518. (*M. maximo flore, foliis subtus ferrugineis*; Trew *Ehret.* t. 33.)—Leaves perennial, coriaceous, oblong. Petals obovate.—Native of North America, from the northern limits of Carolina to the Mississippi. *Michaux.* It seems by the Hort. Kew. not to have been cultivated in this country before the year 1734. This is a very noble evergreen tree, sufficiently hardy, at least in the southern parts of England, or near the sea, only requiring plenty of water to blossom freely. The leaves are scattered, on short thick stalks, elliptic-oblong, more or less pointed at each end, from four to ten inches long, and two or three broad, veiny, very rigid and coriaceous; smooth, shining, and of a full bright green, above; opaque, and sometimes clothed with rusty down, beneath; their margin entire, thickened and somewhat wavy. *Stipulas* solitary, convolute, sheathing, downy, soon deciduous. *Flowers* terminal, solitary, on thick downy stalks, each as large as a pint basin, white, deliciously fragrant like the flavour of cold lemonade. The petals have the texture and aspect of delicate white leather, and shrink very much in drying. These flowers come out in July. The variety with rusty leaves blossoms at an early age, and is therefore most popular; but the great smooth-leaved kind, first brought to this country, of which fine specimens may be seen at Chelsea, Sion house, and other old gardens, is vastly preferable in itself, when it arrives at a sufficient age to produce its much larger flowers.

2. *M. Plumieri*. West Indian Magnolia. Swartz. *Prodr.* 87. *Fl. Ind. Occ.* 997. *Plum. Gen.* as above. (*Talauma*; Juss. 281.)—Leaves perennial, coriaceous, roundish-ovate, smooth on both sides. Flower-stalks smooth. Petals ten or twelve.—Native of the West Indies, observed by Dr. Swartz in St. Lucia, Martinico, and Guadaloupe, where the French call it either *Bois pin*, or *Bois Cachiman*. This author describes it as one of the largest of trees, often 80 feet high. “*Branches* round, annulated, scarred where the leaves have stood, their bark of a greyish-brown. *Leaves* alternate, stalked, large, roundish inclining to ovate, coriaceous, reticulated with veins, smooth on both sides. *Foot-stalks* thick, round, flattish above, smooth and naked. *Flowers* terminal, solitary, very large, white and fragrant, on thick smooth stalks, marked with whitish rings. *Calyx* of three large, ovate, concave, coriaceous, petal-like, veiny, deciduous leaves, externally glaucous. *Petals* from 10 to 12, rather longer than the calyx, oblong, obtuse, concave, thick, contracted at the base.” Dr. Swartz never met with the fruit. Plumier describes and figures the latter as hard and knobby, of a blue colour, lodging in its substance several oblong nuts, each of which contains a kernel of the same shape. Jussieu, who found a specimen in Surian’s collection, with the name of *Talauma*, describes it as “large and ovate, resembling a *srobilus* or cone, composed externally of thick, granulated, corky, permanent scales; while the inner part is woody, hard, hollowed out in its circumference into numerous single-seeded cells, apparently

not bursting, some of them abortive.” These are all the materials we have to judge by. Burman’s ignorance and misplaced economy induced him to omit publishing a figure of the plant in his *Icones* of Plumier; see p. 161 of that book. Swartz seems to have had no suspicion that it could be any thing but a *Magnolia*, though his character and description prove it specifically distinct from the *grandiflora*; to which however it appears to be so very nearly related, that we think it highly improbable there can be any real generic distinctions in the seed-vessel. We find nothing in Plumier or Jussieu, but what may be referred to a not quite ripe, or an ill-understood, fruit of a genuine *Magnolia*. If it should prove otherwise, we have already (see *LOBELIA*) hinted the propriety of not disturbing the name by which the bulk of the species are so well known, and would rather retain for this, if a separate genus, the appellation it has in Jussieu, though of barbarous origin. As the point in dispute is one of the most interesting botanical problems, we wish it may excite the attention of some West Indian traveller.

3. *M. glauca*. Swamp Magnolia. Linn. *Sp. Pl.* 755. (*M. lauri folio subtus albicante*; Trew *Ehret.* t. 9. *Dill. Elth.* 207. t. 168.)—Leaves elliptic-oblong, obtuse, glaucous beneath. Petals obovate.—Native of swampy ground in North America. “From New Jersey to Florida.” *Michaux.* It appears to have been the first of its genus introduced into the gardens of England, having been cultivated by Bishop Compton, at Fulham, in 1688. This is a small tree, very desirable on account of its flowers, which come forth, at the ends of the branches, in July, and are cream-coloured, concave, about two inches wide, with a peculiarly rich vinous fragrance, to some people rather oppressive. The leaves also are beautiful, about three inches long, varying in breadth, veiny; bright green above; glaucous and somewhat silky beneath. In the variety seen in our gardens they are deciduous; in another, of which we have specimens from Carolina, they are evergreen, and of a longer narrower figure.

4. *M. conspicua*. Lily-flowered Magnolia, or Youlan. Ait. n. 3. *Salis. Parad.* t. 38. (*Mokkwuren* 1; Banks *Ic. Kämpf.* t. 43.)—Leaves obovate, obtuse with a point, appearing after the flowers are over.—Presumed to be a native of China, where it has been cultivated for ages, forming a tree 30 or 40 feet high, with zigzag much divided branches, at the end of each of which, in the early spring, before any leaves appear, stands an elegant white lily-like flower, four inches wide, with some of the cool lemon scent of the first species, at least when brought into a warm room. The leaves expand in May, and are flexible, on slender stalks, of a broad obovate or wedge-like figure, with a small tip, each three or four inches, or more, in length. Sir Joseph Banks procured this fine plant from China in 1789. It is hardy in our climate, and is at an early age covered with flowers from February to April, though the severe east winds of the season often injure its beauty, unless it be protected by a frame, or planted in a conservatory.

5. *M. obovata*. Purple Magnolia. Thunb. *Tr. of Linn. Soc.* v. 2. 336. (*M. purpurea*; Curt. *Mag.* t. 390. Andr. *Repos.* t. 324. *M. discolor*; Venten. *Malmis.* t. 24. *M. glauca* β; Thunb. *Jap.* 236. *Mokkwuren*; Kämpf. *Amoen.* 845. Banks *Ic. Kämpf.* t. 44.)—Leaves obovate, pointed, appearing with the flowers. Petals oblong, bluntish.—Native of China, from whence the late duke of Portland is said to have obtained it in 1790. It is tolerably hardy, flowering in May and June, but appears to most advantage in a conservatory. In the shape and habit of its leaves this agrees much with the last, but the flowers are larger, of a fine

MAGNOLIA.

fine purple, darkest at the outside, and do not appear till the foliage is fully expanded; they have little or no scent. Willdenow and Thunberg erroneously consider Kæmpfer's *Ic. t. 43 and 44* as one and the same plant, nor has any one corrected their mistake till now. It is lamentable that Curtis's appropriate name, *purpurea*, has not been preferred to that of Thunberg, whose confounding the present plant with *M. glauca*, rather shakes our confidence in his botanical observations and opinions. It must be presumed that his white-flowered variety is our *M. conspicua*; but in neither of these plants are the leaves glaucous beneath. They are in both, especially their ribs and veins, more or less clothed with short brown hairs.

6. *M. tomentosa*. Slender Woolly Magnolia. Thunb. *Tr. of Linn. Soc. v. 2. 336.* Willd. n. 5. Ait. n. 5. (*M. gracilis*; *Salis. Parad. t. 87.* Kobus; Kæmpf. *Amoen. 845.* *Ic. t. 42.*)—Leaves obovate, pointed, downy beneath, appearing after the flowers. Petals six, oblong, obtuse.—Native of Japan and China, from which last country the late Mr. Greville is said to have received a plant, which blossomed with him in the spring. Mr. Salisbury ascertained the synonym of Kæmpfer, from his herbarium and papers in the British Museum, and has well asserted this to be a distinct species from the last.

7. *M. pumila*. Dwarf Magnolia. Ait. n. 6. Andr. *Repos. t. 226.* Sims in *Curt. Mag. t. 977.* (*Gwillimia indica*; *Rottler MSS.* Sampa Salaca, or Milk Flower, of the Malays.)—Leaves elliptic-lanceolate, pointed, smooth. Petals six, obovate, very blunt, concave. Flower-stalk and calyx smooth, incurved.—Native of China, or rather, as we suspect, of some of the East Indian islands. It is cultivated in China, (from whence the late lady Amelia Hume received a plant about 1786,) as well as at Batavia and Madras, but is never known to produce fruit in any situation in which it has come under the examination of botanists, so that the genus is by no means certain. See what we have already mentioned on this subject under *LIRIODENDRUM liliifera*. The present is a humble, smooth, deciduous shrub, kept in the greenhouse, where it blooms at various periods during summer. The foliage has a glaucous tinge, and is wavy, and finely reticulated with veins. Flowers terminal, drooping, globose, cream-coloured, short-lived, very fragrant at night, most like those of *M. glauca* in shape, but smaller, and with more of a greenish cast. The cells of the anthers are close together, at the inner side, and the whole anther is club-shaped and obtuse, very unlike that of the other species. Mr. Andrews alone has expressed these most important characters.

8. *M. fuscata*. Brown-stalked Magnolia. Andr. *Repos. t. 229.* Sims in *Curt. Mag. t. 1008.* Ait. n. 7. (*M. annæfolia*; *Salis. Parad. t. 5.*)—Leaves elliptic-lanceolate, smooth. Petals six, elliptical, concave. Flower-stalk erect, hairy, as well as the calyx.—Native of China, from whence it was procured by Sir J. Banks, for Kew garden, in 1789. We saw and described the plant about the same time in lady A. Hume's collection. It flowers in the greenhouse from April to July. The stem is of humble growth, with brown hairy branches. Leaves elliptic-lanceolate, sometimes inclining to obovate, about three inches long, smooth, veiny, deciduous except when kept in the stove. Flowers on lateral or axillary hairy rusty stalks, of a dark dull purple, smelling strongly like apples, much smaller than those of *M. pumila*. Anthers with nearly marginal linear cells, opening inwards, as in true *Magnolia*.

9. *M. acuminata*. Blue Magnolia. Linn. *Sp. Pl. 756.* Ait. n. 8. (*M. flore albo, folio majore acuminato, haud albicante*; *Catesb. Carol. v. 3. 15; with a plate.*)—Leaves

ovate-oblong, pointed, downy beneath. Petals more than six, channelled, glaucous.—Native of North America from Pennsylvania to Carolina, upon the loftiest mountains. *Michaux*. Mr. Collinson first introduced it alive into England, in 1736. His original tree was lately in fine perfection at Mill Hill, and we hope still exists there, having escaped the devastation which that interesting spot underwent on its first sale, when ignorance and bad taste contended which should do the most mischief there. The place is now become a school, and its few remaining treasures must be presumed to be in great jeopardy. (See COLLINSON, PETER.) The present species forms a large, umbrageous, deciduous tree, whose wood is yellow. Leaves clustered at the end of each branch, but on its subsequent elongation becoming alternate, stalked, pointed at each end, several inches long, and nearly half as broad; green and smooth above; paler, and at first downy, beneath. The flowers appear among the young leaves early in June, standing solitary, each on a short smooth stalk, at the end of the branches. They are neither fragrant nor beautiful, though remarkable for their pea-green very glaucous petals, which vary in shape, but are always concave, or channelled, and usually about two inches long. The capsule, with its red seeds, hanging by long threads out of their cells, is sometimes ripened in England. We have seen it at Kew.

10. *M. tripetala*. Umbrella Magnolia. Linn. *Sp. Pl. 756.* Ait. n. 10. (*M. foliis ovato-oblongis ad basin et apicem angustis, utrinque virentibus*; *Trew Ehret. t. 62, 63.*)—Leaves lanceolate. Petals nine; the three outermost reflexed and dependent.—Native of Carolina; more rarely of Virginia. Miller appears to have had this tree at Chelsea in 1752, nor is it now uncommon in curious collections. It loves a moist strong soil. The leaves are deciduous, oblong, smooth, light green, tapering at each end, of a very large size, usually 18 inches long at an early period, and finally above two feet, spreading in the form of an umbrella at the end of each branch. Among them, early in June, stands an upright, very large, white flower, remarkable for the three pendulous outer petals, and for its peculiar scent, which Munchausen commends, but most people find insufferable, from its starch-like overwhelming faint sweetness. Ehret compares it to a vast quantity of white lilies. The fruit is not known to have been ripened here.

11. *M. auriculata*. Ear-leaved Magnolia. *Michaux Boreal-Amer. v. 1. 328.* Willd. n. 8. Ait. n. 12. *Anur. Repos. t. 573.* Sims in *Curt. Mag. t. 1206.* (*M. Fraseri*; *Walt. Carol. 159. t. 1.* *M. auricularis*; *Salis. Parad. t. 43.*)—Leaves spatulate-ovate, acute; heart-shaped at the base; smooth beneath. Petals obovate.—Native of lofty mountains in Carolina, from whence it was first brought to England alive by the late Mr. Frazer in 1786. This, like the last, is a tree that flowers at an early age, and their habits are similar. The prominent rounded lobes at the base of the leaves mark the present species. The flowers appear in July, and are large, of a yellowish-white, and delightfully fragrant. Willdenow seems to have taken from the figure in Mr. Walter's book his character of "claws to the petals," for which there is no just foundation, that figure having been faultily drawn, from a dried specimen.

12. *M. macrophylla*. Long-leaved Magnolia. *Michaux Boreal-Amer. v. 1. 327.* Ait. n. 9.—Leaves spatulate-obovate; heart-shaped at the base; glaucous and downy beneath.—Native of North America, to the west of the river Tennessee. *Michaux*. Brought by Mr. Frazer and his son, in 1800, "from the wilderness in Kentucky, on

the banks of the south fork of the Cumberland river."—It flowers in June and July. We have seen but a leaf, which has a round, downy, striated footstalk, full of pith, as Michaux describes all the branches to be. The leaf itself is near 18 inches long, and nine broad, somewhat panduriform, being contracted above the dilated heart-shaped base, and then again extended; the upper surface is green and smooth; the under singularly glaucous, or nearly white, and finely downy; both are minutely reticulated with innumerable veins. Michaux says the petals are six, white, the lower ones purple at their base.

13. *M. cordata*. Heart-leaved Magnolia. Michaux Boreal-Amer. v. 1. 328. Ait. n. 11.—"Leaves heart-shaped, somewhat downy beneath."—Native of dry open hills in Georgia and North Carolina. Michaux. Messrs. Frazer are recorded as having brought it to Kew in 1801, but it has not yet blossomed. Michaux says it is allied to *M. acuminata*, and that the flowers are yellow. We have never seen a specimen. S.

MAGNOLIA, in *Gardening*, contains plants of the evergreen and deciduous tree kinds, of which the species usually cultivated are, the laurel-leaved magnolia (*M. grandiflora*); the swamp deciduous magnolia (*M. glauca*); the blue magnolia (*M. acuminata*); and the umbrella magnolia, or umbrella tree (*M. tripetala*.)

The first sort has varieties with broad leaves, and with narrow leaves.

And in the second kind there is a variety with long leaves, which is evergreen.

Method of Culture.—All these plants may be increased by seed, layers, and cuttings of the shoots.

With regard to the first mode, the seed, which is received annually early in the spring from America, preserved in sand, should be sown, as soon after as possible, in pots of light rich earth, half an inch deep, plunging them in a moderate hot-bed, to bring up the plants an inch or two in height, or in the common earth under a warm wall or hedge, or in a frame, in the full sun, till the middle or latter end of April, then replunging them in an easterly border open to the morning sun; giving moderate sprinklings of water in dry weather. The plants will rise the same year; those in the hot-bed, probably in April, and the others in May, inuring those in the first situation timely to the full air. The plants should, all summer, be regularly supplied with water, and at the approach of winter be removed into a greenhouse, or, rather, under a garden-frame, to be sheltered from frost all winter, indulging them with the open air in mild weather. If the pots be plunged in a bark hot-bed, &c. about March, under a frame, two or three months, it will forward the plants greatly; being careful to give water, and harden them to the open air gradually, so as to be removed into it in their pots fully in June, to remain till the autumn, when they should be allowed shelter in winter, as before. The following spring, they should be planted into separate pots, and plunged into a hot-bed, as before, to set them forward, giving water, occasional shade, and the benefit of free air; and in June removing the pots to a shady border for the remainder of the summer. In winter they should have shelter as before, from severe frost, but have the full air in all open weather. They require the same care for two or three winters, when some of them may be turned out of the pots with balls of earth about their roots, into the full ground, in a warm sheltered situation, particularly the deciduous kinds; but the first, or evergreen sort, should not be too soon exposed to the winter's cold, but be continued in occasional shelter in the above manner four or five years, till two, three, or more feet

high; and when turned out, matted occasionally in severe winters, retaining some in pots to be managed as greenhouse plants of the more hardy kind.

In the layering mode, the layers should be laid down in autumn or spring, choosing the young pliable shoots for the purpose, giving them a gentle twist, or a slit in the part laid into the earth. Some will be well rooted in one year, others probably not in less than two; then take them off, and plant each in a pot in the early spring, plunging them in a moderate hot-bed for a month or two, to promote their growth freely at first, and they will generally form good strong plants by the following autumn, allowing them shelter in winter for a year or two, when they may be planted out.

In the cutting plan, the cuttings should be made from the short young shoots of the preceding year, and be planted in pots of good earth, plunging them to the rims in the common or stove hot-bed, giving water and occasional shade; some of them will be rooted the same year, when they must be inured by degrees to the open air, after which they may be managed as the layers.

It may be noticed that the first, or ever-green sort, is one of the most beautiful trees in nature, both in its growth, and in the luxuriance of its noble leaves, which render it singularly conspicuous at all seasons. And the deciduous sorts are also highly ornamental trees, and may be introduced into clumps and shrubberies, where, by their fine foliage, they exhibit an elegant variety.

In common, all the different species are cultivated in the nurseries, for sale, from which they may be taken up and planted out in the early spring or autumn months; but the former is the better in most cases.

With regard to their disposition in the shrubbery, as they are rather tender in their early growth, they should have a sheltered sunny situation, in a rather dry soil, being planted in the most conspicuous places, and not too closely crowded with other shrubs. But they have a good effect even when disposed singly in different parts, as in open spaces of short grass-ground, in sheltered situations; especially the first sort, from its evergreen nature.

MAGNOLIÆ, in *Botany*, a natural order of plants, so called from the genus *Magnolia*, which makes a principal figure among them, is the seventy-fifth in the system of Jussieu, and the fifteenth of his thirteenth class. See GRANARIA.

The *Magnolia* are thus characterized. *Calyx* of a definite number of leaves, sometimes bracteated. *Petals* generally of a definite number, truly inserted below the germen. *Stamens* numerous, distinct, with the same insertion; anthers coalescing with the filaments. *Germens* several, either definite or indefinite in number, placed on a common receptacle; styles either one to each germen, or wanting; stigmas one to each germen. *Capsules* or *berries* as many as there are germens, of one cell, containing one or many seeds; sometimes the pericarps coalesce into one single fruit. *Embryo* of the seed straight, destitute of albumen. *Stem* shrubby or arborecent. *Leaves* alternate, mostly undivided, the younger ones sheathed by stipulas which embrace the branch, being convoluted in the form of a horn, as in the Fig genus, and protecting the bud, which is terminal. These stipulas, however, soon fall off, leaving a circular scar. The flowers are either terminal or axillary.

The genera referred by Jussieu to this order are *Euryandra* of Forster, which Schreber makes a *Tetracera*, i. e. EURYANDRA; *Drymis* of Forster, the *Winters* of Schreber; *Allicium*, *Michelia*, and *Magnolia* of Linnæus; *Talauma* of Jussieu, which is the original *Magnolia* of Plumier; *Liriodendron*

Jendrum of Linnæus; and *Mayna* of Aublet, Lam. Illustr. t. 491.

To these are subjoined as akin to them, *Dillenia*, *Curatella*, *Ochna*, and *Quassia*.

MAGNON, JOHN, in *Biography*, a French poet and advocate, who exercised his profession some time at Lyons, and then quitted it for dramatic writing, was born at Tour-nay. He was assassinated in 1662, in the streets of Paris. He is mentioned as the person who projected, but did not live to complete, an Encyclopédie in verse. Moreri.

MAGNOTS, or MAINOTS, in *Geography*, an appellation distinguishing Greeks, who inhabit the south part of the Môrea, the environs of Sparta, and more particularly the part which extends from Mistra to Cape Matapan. As remains of the Lacedæmonians, they are as ardent as their ancestors in defending their liberty and maintaining their independence. The Turks have sometimes obtained a trifling tribute from them, without ever having been able entirely to subdue them. Cultivators or shepherds, mariners or pirates, according to the exigence of their circumstances, they are always ready to quit the small towns which they occupy on the gulfs of Coron and of Colokythia, for the purpose of penetrating into the interior of the country, and establishing themselves on the mountains. With this energy and love of liberty, it is to be regretted, that there are among them robbers, who, not content with making war on the Turks, who have unjustly dispossessed them of a part of their territory, also go sometimes to plunder the unfortunate Greeks of the small islands of the Archipelago, who ought rather, on account of identity of religion and of interest, to unite against their common enemies.

MAGNUM OS, in *Anatomy*, a name of one of the bones of the carpus. See its description in the article EXTR-
MITIES.

MAGNUS, JOHN, in *Biography*, archbishop of Upsal, in Sweden, was born in 1483. He opposed most strenuously the Reformation in Sweden, and finding his efforts ineffectual, he retired to Rome, where he died in 1544. He wrote a history of Sweden, and lives of the archbishops of Upsal: he had a brother Olaus, who was one of the persons at the council of Trent, where he displayed considerable talents for business. He died at Rome in 1560. His greatest work is a History of the Northern Nations.

MAGNUS, organist of the church of St. Giles-in-the-Fields, who flourished about the year 1730, was esteemed, by his contemporaries, a great master of harmony, and an admirable extempore player on the organ; of whose great abilities many years after his decease we have often heard Rouin-grave and Dr. Arne speak with rapture. Before Kelway and Stanley were arrived at great renown, which they afterwards acquired by their voluntary playing, Magnus drew crowds of young organists to St. Giles's every Sunday to hear him on the full organ, on which, despising single solo stops, he had attained to such command, as to be able to conduct four parts in fugue, with as much correctness and facility, as others could two parts, without fugue or imitation. Excessive study and application brought on a disorder in his intellects, which put an end to his existence; at an early period of his life.

MAGNY, in *Geography*, a town of France, in the department of the Seine and Oise, and chief place of a canton, in the district of Mantes; 12 miles N. of Mantes. The place contains 1402, and the canton 11,149 inhabitants, on a territory of 222½ kilometres, in 29 communes.

MAGO, a town of the island of Ceylon, near the S.E. coast; 98 miles S.S.E. of Candy.

MAGOAR, a town of France, in the department of the North Coasts; 10 miles S. of Guingamp.

MAGODUS, among the Romans, a name given to those players who sometimes acted the part of men, and sometimes of women: the word is derived from *μαγος*, *magic*, and *αδης*, *singer*, and properly denotes those players who performed extraordinary feats and gestures.

MAGOLSHEIM, in *Geography*, a town of Germany, in the kingdom of Wurtemberg; 30 miles S. of Stuttgart.

MAGON, a town of the island of Minorca, said to have been founded by the Carthaginians.

MAGONA, in *Ornithology*, the name given by Buffon to the Macaragua of Maregrave, Ray, &c. and the great Tinamou of Latham. See TETRAO *Major*.

MAGOPHONIA, formed from *μαγος*, *magus*, and *φονος*, *slaughter*, the name of a feast among the ancient Persians, held in memory of the expulsion of the Magians.

The Magus Smerdis having usurped the throne of Persia upon the death of Cambyses, 521 years before Jesus Christ, seven of the principal lords of the court conspired to drive him out of it. Their design was executed with good success: Smerdis, and his brother, another Magus, called Patizithes, were killed. Upon which the people also rose, and put all the Magi to the sword; inasmuch that there would not have one escaped, had not night come upon them. Darius, son of Hystaspes, was then elected king: and, in memory of this massacre of the Magi, a feast was instituted, says Herodotus, called *Magophonias*. See MAGI.

MAGORA, in *Geography*, a town of Walachia; 14 miles S.E. of Rusei.—Also, a sea-port of Arabia, in the Red sea; 150 miles N.N.W. of Loheia. N. lat. 17° 40'.

MAGOT, in *Zoology*, the name given by Buffon to the Barbary ape of Pennant, or the *SIMIA Inuus*; which see.

MAGOTTY COVE, in *Geography*, a bay on the N. coast of Jamaica; one mile W. of Musketto cove.

MAGPIE RIVER, a river of Canada, which runs into the gulf of St. Lawrence, about six miles W. from the mouth of the river St. John.

MAGPYE, in *Ornithology*, a well-known species of the *Corvus*, or the *corvus pica*, in the Linnæan system: it is a crafty, restless, noisy bird, called by Ovid *memorum convicia pica*. See *CORVUS PICA*.

MAGRA, in *Geography*, barren mountains of Africa, on the road from Tripoli to Egypt; 150 miles W. of Cairo.

MAGRA, or *Magora*; a river of Italy, which rises in the Apennines, and passing through a valley, called the "valley of Magra," runs into the sea, five miles S. of Sarzana.

MAGRACOTTA, a town of Hindoostan, five miles W. of Palicaudcherry.

MAGRE, a town of Hindoostan, in the Mysore country, deemed by the Hindoos a place of peculiar sanctity, and abounding in pagodas and choultries; six miles from Savindroog.

MAGREBIANS. See MOGRABIANS.

MAGUA, a town of Hindoostan, in Dowlatabad; five miles S. of Beder.

MAGUALBARI, or RIO DAS GALINES, a river of Africa, in Guinea, which runs into the Atlantic, N. lat. 7°.

MAGUANA, St. JOHN of, a canton and town on the S. side of the island of St. Domingo, on the left side of the river Neybe. The capital of the ancient kingdom of Maguana stood where the town St. John of Maguana is now situated. This canton was pillaged by the English privateers in 1543. In 1764, the district of the new parish contained 3600 persons, of whom 300 were capable of bear-

ing arms. Its population now amounts to more than 5000 persons.

MAGUANA. See MAYAGUANA.

MAGUARI, in *Ornithology*. See *CICONIA Americana*.

MAGUDARIS, a name by which Dioscorides calls the silphium.

MAGUELONE, in *Geography*, a lake of France, in the department of the Gard, near the Mediterranean, communicating with it, and extending from Catte to Pecais. Its name is derived from that of an ancient town, which was a bishop's see, transferred in 1538 to Montpellier. Charles Martel destroyed the town, because it was an asylum for Saracen invaders. It was rebuilt in the year 1060, but is now a small place, situated on a neck of land between the lake and the sea; five miles S. of Montpellier. N. lat. $43^{\circ} 30'$. E. long. $3^{\circ} 58'$.

MAGUIBA, a river of Africa, that runs into the sea, E. of cape Monte.

MAGULLACONDA, a town of Hindoostan, in Mysore; 30 miles from Chinna Balabaram.

MAGUMBA, a province of Africa, in the N.W. part of the kingdom of Loango.

MAGYDARIS, in *Botany*, a name used by Theophrastus, and other of the old authors, for the laferpitium or laferwort.

MA-HA, or MA-COUPA, in *Geography*, a city of China, of the second rank, in Kooi-tcheou. N. lat. $26^{\circ} 26'$. E. long. 107° .

MAHABARAT, an epic poem in the Sanskrita language, by an author very celebrated among all sects of Hindoos, named Vyasa, to whom also is ascribed the sacred romances, the Puranas. (See *VYASA* and *PURANA*.) The subject of the Mahabarata is the heroic adventures of the five sons of Pandu, called hence the Pandavas. (See *PANDU*.) It is a work of great extent, amounting it is said to upwards of a hundred thousand metrical stanzas, of which more than a third have been translated by Dr. Wilkins, librarian to the East India company. This learned gentleman published in 1785, an episode of the great poem, under the title of "Bhagavat Gita, or Dialogues of Krishna and Arjun." An extract from that very curious work is given under the article *KRISHNA*. The Mahabarata contains the genealogy and general history of the house of Bhaurat, so named from Bharat its founder, the epithet Maha, or great, being prefixed in token of distinction; but its more particular object is to relate the dissensions and wars of the two great collateral branches of it, called from their ancestors the Kurus and Pandus (see *KURU*), both lineally descended in the second degree from Vichitravirya, their common ancestor, by their respective fathers Dritrashtra and Pandu. In the dedication of the Bhagavat Gita, Mr. Warren Hastings, under whose auspices the translation was made, after noticing the banishment of the Pandus, says, "The exiles, after a series of adventures, worked up with a wonderful fertility of genius and pomp of language into a thousand sublime descriptions, returned with a powerful army to avenge their wrongs, and to assert their pretensions to the empire in right of their father. In this state the episode opens." Without allowing the antiquity of four or five thousand years as claimed by the Hindoo literati for their justly admired Mahabarata, its great age is unquestionable. In general estimation it ranks next to the Ramayana, if it be not superior to it, in reputation for holiness: the Vedas and Puranas only precede these works in the estimation of a great portion of the Hindoos. See *RAMAYANA*.

Mr. Moor, in his Hindoo Pantheon, after noticing the allegorical character of Oriental mythology, says, "This may serve as a farther specimen of the endless allegories in which the poetical fabulists have veiled the moral, scientific, and theological knowledge of the Hindoos; all of which, as well as history, and even arts, if not buried in, are obscured by, and intimately connected with, their wild and bold mythology. Thus, again, the Mahabarata is a continued allegory of the conflicts between man's virtues and his vices: the former personified under the names of the five sons of Pandu; of whom Bhima, Yudistira, and Arjun, said to represent Justice, Fortitude, and Prudence, were by one mother, Kooni; and the other two, Nakal and Sahadeva, personifications of Temperance and Wisdom, were by Maderi. (See *KOONTI* and *MADERI*.) Other legends attribute the virtues of Modesty and Tenderness to Yudistira; Strength to Bhima; and Skill or Courage to Arjun; to Nakal, Beauty or Harmony; and to Sahadeva, Wisdom and Penetration. The two last brothers are by some said to be the twin virtues of Temperance and Chastity. Man's manifold vices are personated by the hundred sons of Kuru, the brother of Pandu: hence a near relationship exists between Vice and Virtue." P. 92.

MAHABELI, a name in Hindoo mythological legends of a monarch who, although reasonably virtuous on other points, was still so elated by his grandeur, that he omitted the essential ceremonies and offerings to the deities; and Vishnu found it necessary to check the influence of such an example, by resolving to become, for that purpose, incarnated in the person of a wretched Brahman dwarf. This incarnation, or avatara, is one of the ten principal descents of Vishnu, and is called Vamana, or the dwarf. (See *VAMANA* and *VISHNU*.) Sir William Jones surmises the Belus of western history, to be the same with the Beli of this article, for the epithet of Maha prefixed, merely means great in the Sanskrita language.

MAHABUTPOUR, in *Geography*, a town of Bengal; 33 miles S. of Dacca.

MAHACKAMACK, a river of America, which falls into the Delaware from the N.E. at the N.W. corner of New Jersey.

MAHACONDAPALLY, a town of Hindoostan, in Mysore; 15 miles S. of Oussloor.

MAHADEO, a temple of Thibet, situated on the lake Manfaroar.

MAHA-DEVA, in *Hindoo Mythology*, is a name given to the god Siva, one of the persons in their divine triad. (See *SIVA*.) In Sanskrit it means literally the great god; and although we might expect to find this name thus applied by the sect only, who exclusively worship Siva, indicating the pre-eminence of their deity, yet it is said to be commonly given to him by other sects, as well as by his own.

MAHAKALA, a name of Siva, the destructive attribute of the deity. The name seems to be the same as Kal or Kala (which see), with an epithet prefixed, meaning great. Mr. Pateron, in the eighth volume of the Asiatic Researches, thus describes this personification. "Mahal Kal, as represented in the caverns of Elephanta, had eight arms. In one he holds a human figure, in another a sword, or sacrificial axe; in a third he holds a basin of blood, and with a fourth he rings over it the sacrificial bell. Two other arms are broken off; with the two remaining he is drawing behind him a veil, which extinguishes the sun, and involves the whole universe in one undistinguished ruin. One of the titles of this tremendous deity is Bhairava, the Terrific; but his principal

principal designation is Kal-Agni-Rudra." These three words, we are told in the Hindoo Pantheon, are especially descriptive of Siva, and may be rendered Time, Fire, Fate. See KAL.

Niebuhr gives a print in his *Indian Travels* of the sculpture above described, which Maurice has copied into his sixth volume of *Indian Antiquities*. In the Hindoo Pantheon, the following description is given of this subject from the personal examination of the author. "Having lately been in the Elephanta cavern, and when there made some memoranda, I will thence extract what relates to the subject of Mahakala.—The compartment containing the group, of which Siva in this character makes the principal figure, is on the right of the entrance, facing a compartment of like size, containing what, in another part of this work, I have supposed to be a marriage ceremony. The figure is of Siva *Vindex*, fourteen feet high, but the lower extremities broken off; his attention is from his attitude turned to his left, his aspect is terrific, indicating the immediate execution of some avenging act,—he had eight arms; the superior right and left stretched upwards, and either supporting a cloth or curtain, or putting it over the terrible event he threatens—the fingers grasp the cloth. The left upstretched arm is finely executed; the right is broken at the elbow: the next right hand is broken off at the wrist; the corresponding left holds a bell, in good preservation, over a cup in the palm of the next, having a serpent twining near the elbow. A third right hand grasps a long straight sword, uplifted, perfect; the two inferior hands, right and left, are broken off above the elbow: they were in bolder relief, and the left appears to have supported, or to have grasped, the leg of a kneeling figure, the trunk only of which remains; its legs, arms, and head being broken off. This kneeling figure may have been between five and six feet in height; its back is toward the threatener, and leaning so in his direction, as to drop its blood, if spilled, into the cup before noticed. The head of the principal figure has a highly ornamented cap; a scull and serpent are among its frontal ornaments. It has also a pendent necklace, and a chaplet, if it may be so called, of human heads, of which only two or three are plainly discernible, flowing over the left shoulder to the right thigh, where it is broken off: the Zennar, or holy thread (see ZENNAR), and a broader belt, run in nearly a like direction. On all the wrists are bracelets, and above the elbows of three of the arms is the ornament called bazuband. No figures remain in any preservation to the right of the principal, or under him. On the left, near the supposed victim, are two bearded faces, expressive of Pity; a compassionate female is just above them, leaning forward over the victim; she holds her scarf in her hands, and is an elegant person: below the bearded men are two or three females with pitying aspects: the same emotion, intermingled with terror, is evident in every face of this compartment, where features can be traced.

"Over the subjects just described, is a row of males and females of rather diminutive size; in the middle of the row, nearly over the head of Siva, is a thing like a mitre, with a crozier cut deep in it, and surmounted with a cross; but the limbs of the cross not exactly at right angles; two aged and emaciated figures are on the right (the spectator's right) of the mitre, holding up their hands betokening pity and pain: on the other side of the mitre are two similar figures; in front of each pair is a prostrate distressed male child, their heads near the mitre: beyond the last mentioned pair, on the spectator's left, are a male and female in great anxiety and distress, holding scarfs in their hands.

"The subject, supposed to resemble a mitre, crozier, and

cross, appears also in another compartment of this cavern. Fancy may, perhaps, have had some share in making this resemblance; but it is really curious, and I think striking, although, I believe, heretofore not remarked." Hin. Pan. p. 51.

The great antiquity of the cavern wherein is this curious piece of sculpture is unquestionable, although no period approaching to exactness can be assigned for its origin. The Hindoos, and their Brahmans, with their accustomed proneness to hyperbole, throw it back into very remote ages: and some of our missionaries and other European travellers, as if unwilling to be outdone in extravagance, have imagined the figure here described of Mahakala destroying a human being, typical perhaps of Time and the human race, to be a representation of the judgment of Solomon! Without stopping here to discuss such ill-judged speculations, similar instances of which will be found under our article KRISHNA; it may be sufficient to notice the progress that the art of sculpture had made in India in times certainly very remote in reference to art and science. The compartment described in the preceding extracts is elaborate in figures powerfully expressing one emotion of the mind; a precision strongly indicating great refinement and skill. It may be reasonably questioned if any specimen equal in age and execution can be elsewhere pointed out. Of the cavern temples of India, some account is given under the articles ELEPHANTA, ELORA, and KARLY.

MAHAKALI, a name of *Parvati*, the consort of *Siva*, in his character of *Mahakala*; under which articles, and *Kal* and *Kali*, farther information may be sought.

MAHA-LAKSHMI, a name given by certain sects of Hindoos to *Lakshmi*, the consort of *Vishnu*. See those articles. Under this name she is worshipped at a pretty temple on the western sea-shore of the island of Bombay, which is much resorted to at the annual *jatra*, or fair.

MAHALEB, in the *Materia Medica*, the name of the fruit of a sort of wild cherry, called *cerajus sylvestris amara*, or the wild bitter cherry, by Bauhin. The wood of the tree is of a greyish cast, and fine grain, with a mixture of red in the veins, and is very firm, and of a sweet smell, and used by the French in making cabinets; the leaves and flower carry a rude resemblance of those of the common cherry; the fruit is round, black, and resembles a cherry, having the same sort of stone in it, the kernel of which is like the bitter almond in taste. It is commended in external applications, and the perfumers of France use it in their washballs. It is to be chosen fresh and sweet, for it very often has an intolerable stinking smell, like that of bugs. See PRUNUS.

MAHALOULE CASSIR, in *Geography*, a town of Africa, in the kingdom of Tunis; 9 miles E. of Zungbar.

MAHAMAIL, a town of Algiers; 27 miles W.S.W. of Tipfa.

MAHAMMA, a town of Arabia, in the province of Yemen; 24 miles S.E. of Chamir.

MAHAMUNDALA, a town of Hindoostan, in the Carnatic; 10 miles S. of Chittoor.

MAHAN, a town of Persia, in the province of Kerman; 60 miles N.E. of Sirjan.

MAHANADA, or MAHA-NUDDY, a river of Hindoostan, which rises in the mountains of Berar, in the country of Ruttunpour, traverses the country of Orissa, passes by Cattaek, where it is sometimes called the Cattaek river, and discharges itself by several mouths into the bay of Bengal; 40 miles E.S.E. of Cattaek. The farthest point to which it is navigable from the sea is Arung. Near this river is the fort called *Boad*, and a town called *Beiragur*, which

see

see respectively. The mouths of the river, which form an assemblage of low woody islands, like the Ganges, and many other rivers, have never been traced, but are described merely from report. At the mouth of the principal channel, near Falso point, is a fortified island, named Cojung, or Codjung. Ptolemy's *Adamas* river answers perfectly to the Mahanuddy; and the district "Sabaræ," on its banks, is said to abound in diamonds.

MAHANĒDA, a river of Hindoostan, which rises on the borders of Bootan, and runs into the Ganges; 20 miles N. of Moorshedabad.

MAHANAGORE, a town of Bengal; 20 miles N. of Islamabad.

MAHANAIM, or **MANAIM**, in *Ancient Geography*, a city of Palestine, belonging to the Levites, of the family of Merari, in the tribe of Gad, on the brook Jabok. (Josh. xxi. 33, xiii. 29, 30. 1 Chron. vi. 80.) Jacob gave it this name, because he had here a vision of angels. (Gen. xxxii. 2.) In the Vulgate it is sometimes called simply "Castra," or the camp. Gen. xxxii. 2. 2 Sam. ii. 8. 12. 29. xvii. 24. xix. 32.

MAHANASAN, in *Geography*, a city of Persia, in the province of Mazanderan, composed of three towns joined together. In 1392 it was taken, pillaged, and destroyed by Timur Bec; 12 miles N.E. of Amol.

MAHANDPOUR, a town of Hindoostan, in the circle of Chanderee; 38 miles W. of Chanderee.

MAHANGANO, a province of Africa, in the kingdom of Angola, having a capital of the same name.

MAHANY, a river of Hindoostan, in Bahar, which runs into the Ganges, about 25 miles below Bar.

MAHAPRALAYA, in *Metaphysics*, is considered among Hindoo philosophers as the grand consummation of all things: the great destruction, as the word appears to mean. See hereon under **KAL**.

MAHARSHIS, an appellation applied in Hindoo books to departed sages or faints. The terms Devarshi, Rajarshi, and Maharshi, seem nearly synonymous with Rishi, meaning faint, deified faint, great faint, or great sage. There are differences doubtless, for Nareda is reckoned the chief of the Devarshis. Krishna in the Bhagavat Gita (see **MAHABARAT**) speaks of his "holy servants the Brahmans and the Rajarshis," and says "I am Brighu among the Maharshis, and of all the Devarshis I am Nared," p. 86. (See **NAREDA**.) Nareda and Brighu are generally called sons of Brahma. The term Maharshi occurring in the sixth section of the first book of the Ramayan, the learned translators subjoin the following note—"There are four kinds of sages or Rishis: the Rajarshi, or royal sage; the Maharshi, or great sage; the Brahmashri, or sacred sage; and the Devarshi, or divine sage: of these the first is esteemed the lowest, and the last the highest." Hindoo Pantheon, p. 95. (See **RISHI**.) The names of these sages, and allusions to them, occur frequently in the writings of the Hindoos.

MAHA-RUDRA, in *Hindoo Mythology*, a name of Siva. It means the great Rudra. See **SIVA** and **RUDRA**.

MAHAUT BAY, in *Geography*, a bay on the W. coast of the island of St. Vincent, S. of Cumberland bay.

MAHAWA GAUT, a mountain of Bahar; 24 miles W. of Saferam.

MAHBROOK, a town of Africa, in the Sahara; 160 miles W.N.W. of Tombutoo. N. lat. 19° 10'. E. long. 15°.

MAHBUB, in *Commerce*, a Turkish gold coin. See **SEQUIN**.

MAHDIA, in *Geography*. See **MAADIÉ**.

MAHE, a town and fortress of Hindoostan, on the

coast of Malabar. Mount Dilla, which is a remarkable promontory, situated in N. lat. 12° 1'. E. long. 75° 2', or 1° W. of Cochin, appears to be W. 33° 15' N., or nearly N.W. by W. from Mahé, distant from it 28.4 geographical miles. N. lat. 11° 45' 18". E. long. 75° 26' 30".—Also, a small island in the Indian sea. S. lat. 4° 45'. E. long. 55° 30'.

MAHENDRA, a name of the Hindoo deity *Indra*; which see.

MAHERNIA, in *Botany*, is of uncertain derivation, unless, as professor Martyn says, it be fancifully considered as an anagrammatic inversion of *Hermannia*; the two genera being very nearly allied, or rather, in reality, scarcely to be separated.—Linn. Mant. 8. Schreb. 208. Willd. Sp. Pl. v. 1. 1564. Mart. Mill. Dict. v. 3. Ait. Hort. Kew. ed. 2. v. 2. 198. Juss. 290. Lamarck Illustr. t. 218—Class and order, *Pentandria Pentagynia*. Nat. Ord. *Columnifera*, Linn. *Tiliacea*, Juss.

Gen. Ch. *Cal.* Perianth of one leaf, bell-shaped, permanent, cut into five, awl-shaped, longish teeth. *Cor.* Petals five, heart-shaped, oblong, spreading, twice as long as the calyx. Nectaries five, orbiculate, on stalks, surrounding the germen, shorter than the calyx. *Stam.* Filaments five, capillary, placed upon the nectaries, shorter than the calyx; anthers oblong; pointed, erect. *Pist.* Germen on a short stalk, obovate, five-sided; styles five, bristly-shaped, erect, the length of the petals; stigmas simple. *Peric.* Capsule ovate, of five cells, and five valves. *Seeds* few, kidney-shaped.

Ess. Ch. Calyx five-toothed. Petals five. Nectaries five, joined at the base, orbiculate, placed under the filaments. Capsule of five cells.

The following examples will be sufficient for the illustration of this dubious genus.

M. verticillata. Linn. Mant. 59. Cavan. Diss. fasc. 6. 324. t. 176. f. 1. (*Hermania ciliaris*; Linn. Suppl. 302.)—Leaves in whorls, linear and pinnatifid. Flowers in pairs, on long stalks.—A native of the Cape of Good Hope.—Linnæus describes this plant in these words. "Stem shrubby, diffuse. Branches thread-shaped. Leaves frequently from eight to ten in a whorl, linear, slightly divided or pinnatifid. Inflorescence the same as in *Hermania*, terminal, the stalks generally two-flowered. Corolla yellow.—Take away the nectaries from the petals, and add them to the stamens, and you will have a *Hermannia*, (paradoxical as it may seem) with whorled leaves. What a strange generic metamorphosis!"

M. pinnata. Linn. Syst. Veg. ed. 14. 308. Curt. Mag. t. 277.—Leaves three-parted, pinnatifid.—A native of the Cape, whence it was introduced by M. P. Miller, in 1752. It flowers from June to August.—Stem shrubby, nearly three feet in height. Branches slender and delicate, with a reddish bark. Flowers in clusters, lateral, of a lively red colour when first expanded, drooping like little bells, mostly two together. Linnæus originally esteemed this a species of *Hermannia*.

M. incisa. Willd. n. 5. Curt. Mag. t. 353. Jacq. Hort. Schoenb. v. 1. 28. t. 54.—Stem erect, rough. Leaves pinnatifid, cut and hairy.—A native of the Cape, flowering through the summer and autumn.—Nearly allied to the last in size and habit, but differs in the singular hairiness of its stalks, form of its leaves, and colour of its flowers. Stem, when viewed with a magnifying glass, beset with little protuberances from whence issue tufts of pellucid hairs. Leaves deeply jagged at their edges. Flowers, when in bud, of a rich crimson colour, but, when expanded, of a deep orange, becoming yellow as they fade.

M. glabrata.

M. glabrata. Willd. n. 6. Ait. Hort. Kew. ed. 2. n. 4. (*M. odorata*; Andr. Bot. Repof. t. 85.)—Leaves lanceolate, pinnatifid and toothed. Stalks very long, bearing two flowers.—Found also at the Cape. It blooms in the summer.—This species was first sent to England about 1792.—*Stem* twiggy, and branched. *Leaves* dark green, the upper ones simple and opposite. *Flowers* yellow, fragrant like the Jonquil.

The remaining species of *Mahernia*, enumerated by Willdenow, are, *pulchella*, *diffusa*, *heterophylla* and *biserrata*.

MAHERNIA, in *Gardening*, comprises plants of the shrubby exotic kind, for the green-house, of which the species cultivated are, the wing-leaved mahernia (*M. pinnata*); and the cut-leaved mahernia (*M. incisa*.)

Method of Culture.—These different plants may be increased by planting cuttings of the young branches in the summer season singly, in pots of light mould, watering, and plunging them in a hot-bed till they have stricken root. When they have been well rooted, they may be removed into the green-house for protection during the winter season; being managed as the less tender plants of this description.

All of them afford variety among other potted plants of a similar kind in green-house collections.

MAHESA and MAHESWARA, in *Mythology*, names of the Hindoo god Siva; the same, indeed, as *Isa* and *Isfvara* (which see) with the epithet Maha, or great, prefixed. These names and allusions to them occur perpetually in Hindoo books. The following example from the Gita Govinda of Jayadeva, (see JAYADEVA,) as translated by sir William Jones, shews their prevalence, and is descriptive also of the appearance and attributes of Mahesa, or Mahadeva, and of Krishna. (See KRISHNA.) The last-named deity, agonized by the jealous anger of Radha, exclaims "Grant me but a sight of thee, O lovely Radhika! for my passion torments me. I am not the terrible Mahesa; a garland of water lilies, with subtle threads, decks my shoulders, not serpents with twisted folds: the blue petals of the lotos glitter on my neck, not the azure gleam of poison: powdered sandal wood is sprinkled on my limbs; not pale ashes. O god of love, mistake me not for Mahadeva; wound me not again (see the fable here alluded to, under article KAMA); approach me not in anger; hold not in thy hand the shaft barbed with an amra flower. My heart is already pierced by arrows from Radha's eyes, black and keen as those of an antelope; yet mine eyes are not gratified by her presence. Her's are full of shafts; her eyebrows are bows, and the tips of her ears are filken strings: thus armed by Ananga (or Kama) the god of desire, she marches, herself a goddess, to ensure his triumph over the vanquished universe. I meditate on her delightful embrace; on the ravishing glances darted from the fragrant lotos of her mouth; on her nectar-dropping speech; on her lips, ruddy as the berries of the bimba." See RADHA.

MAHESRA, in *Geography*, a town of Hindoostan, in Mewat; 15 miles S.W. of Cottia.

MAHESWARI, in *Hindoo Mythology*, a name of Parvati, as the Sakti, or consort of Siva, in his character of *Mahesita*, which see. She is represented, like her lord, four-armed, holding a trident, with a vast serpent for a ring, a crescent for a gem, and riding on a bull. She is reckoned one of the Matris, or divine mothers of the celestials. See MATHI.

MAHRA, in *Geography*, a district of Arabia, included by the Arabians within the province of Hadramaut. This district seems, like Tehama, to be a sandy plain, extending in breadth from the shores of the ocean, backward to the part

in which the hilly country commences. These plains have probably been once covered by the sea.

MAHIDESER, a town of Persia, in the province of Irak; 78 miles S.W. of Hamadan.

MAHIE, the name given by the inhabitants of Otaheite, or George's island, to their bread-fruit when made into a kind of four paste, which, in consequence of having undergone a fermentation, will keep a considerable time, and supply them with food when no ripe fruit is to be had. When, therefore, they see a great show of new fruit on the trees, they strip them all at once of their former crop, of which they make mahie. This succedaneum for ripe bread fruit is thus made. They gather the fruit before it be perfectly ripe, and laying it in heaps cover it closely with leaves. In this state it ferments, and becomes disagreeably sweet; the core is then taken out entire, and the rest of the fruit thrown into a hole in their houses, dug on purpose, and neatly lined in the bottom and sides with grats. The whole is then covered with leaves, and heavy stones are laid upon them. In this state it undergoes a second fermentation, and becomes sour, after which it will suffer no change for many months. It is taken out of this hole, as it is wanted for use, and being made into balls, it is wrapped up into leaves and baked, and thus dressed it will keep for five or six weeks. It is eaten, both cold and hot, and the natives of those countries seldom make a meal without it: but to captain Cook and his company the taste was as disagreeable as that of a pickled olive generally is, the first time it is eaten. Hawkesworth's Account, &c. vol. ii. p. 145, 193.

MAHIM, in *Geography*, a town of Hindoostan, in the northern part of the island of Bombay, with a custom house; 17 miles N. of Bombay.

MAHIM, *Mahem*, *Maihem*, or *Mayhem*, in *Law*, a *maim*, or corporal hurt, whereby a man loseth the use of any member, that is, or may be, of defence to him in battle; as, besides arms and legs, the eye, hand, foot, scalp of the head, fore-tooth; or, as some say, a finger or toe: but the cutting off his ear or nose, or loss of his jaw-teeth, are not held to be mayhems at common law, because they do not weaken but only disfigure him. (Finch L. 204. 1 Hawk. P. C. 111.) The word comes from the French *mehain*, of *mehaigner*, to mutilate: the canonists call it *membri mutilatio*; and all agree it consists in the loss of a member, or of the use thereof.

By the ancient law of England, he that maimed any man was sentenced to lose the like part, (*membrum pro membro*) which is still the law in Sweden; but this was disused, and mayhem, by the common law, (1 Hawk. P. C. 112.) was only punishable by fine and imprisonment; unless perhaps the offence of mayhem by castration, which all our old writers held to be felony. But by subsequent statutes the crime and punishment of mayhem were put more out of doubt. By 5 Hen. IV. cap. 5. cutting out the tongue, or putting out the eyes of a man, to prevent him being an evidence against those who beat, wounded, or robbed him, was an offence declared to be felony, if done of malice prepense, that is, as sir Edward Coke explains it, voluntarily, and of a set purpose, though done upon sudden occasion. The statute 37 Hen. VIII. c. 6. directs, that if a man shall maliciously and unlawfully cut off the ear of any of the king's subjects, he shall not only forfeit treble damages to the party grieved, to be recovered by action of trespass at common law, as a civil satisfaction; but also 10*l.* by way of fine to the king, which was his criminal amercement; and by 22 and 23 Car. II. c. 1, called the Coventry Act, it is enacted, that if any one shall of malice aforethought, or by lying in wait, cut

out or disable the tongue, put out an eye, slit the nose, cut off the nose or lip, or cut off or disable any limb or member of another person, with intention in so doing to maim or disfigure him, it is felony without benefit of clergy in such offender, his counsellors, aiders and abettors; and, when the case is difficult to judge whether it be a maim, or not, the judges commonly view the party wounded, and sometimes take the opinion of the surgeons. 2 Roll. Abr. 578. (See EXAMINATION.) By analogy to this, in an action of trespass for mayhem, the count (upon view of such maim as the plaintiff has laid in his declaration, or which is certified by the judges who tried the cause to be the same as was given in evidence to the jury) may increase the damages at their own discretion. 1. Sid. 108.

A person who maims himself, for the purpose of begging, and also a person who disables himself, that he may not be impressed for a soldier, may be indicted and fined. The offence of wilfully and maliciously shooting at any person, which may endanger either killing or maiming him, though no such evil consequence ensues, is made felony without benefit of clergy, by 9 Geo. I. c. 22.

A horrible practice having of late years prevailed among pickpockets and others, of lacerating those who were the objects of depredation or resentment, and the laws being found inadequate to reach and efficiently correct the evil, the legislature interfered, and by the 43 G. III. c. 58. (commonly called lord Ellenborough's act) which recites that divers cruel and barbarous outrages had been of late wickedly and wantonly committed upon the persons of his majesty's subjects, either with intent to murder, to rob, or to maim, disfigure or disable, or to do other grievous bodily harm to such subjects, and that the provisions by law made for the prevention of such offences had been found ineffectual for that purpose, it is enacted that if any person or persons shall wilfully, maliciously, and unlawfully stab or cut any of his majesty's subjects, with intent in so doing, or by means thereof to murder or to rob, or to maim, disfigure, or disable such subject or subjects, or with intent to do some other grievous bodily harm, or to obstruct, resist, or prevent the lawful apprehension and detainer of the person or persons so stabbing or cutting, or of any of his, her, or their accomplices, for any offences for which he, she, or they may respectively be liable by law to be apprehended, imprisoned, or detained; such persons so offending, their counsellors, aiders, and abettors, knowing of or privy to such offence, shall be felons, and suffer death without benefit of clergy. Provided, that if it appear on the trial, that such acts of stabbing or cutting were committed under such circumstances as that, if death had ensued therefrom, the same would not have amounted to murder, in such cases, the person or persons so indicted shall be deemed not guilty of the felonies whereof they shall be so indicted, but be thereof acquitted. § 1.

If the maim come not within any of the descriptions in either of these acts, yet it is indictable at the common law, and may be punished by fine and imprisonment; or an appeal may be brought for it at the common law; in which the party injured shall recover his damages; or he may bring an action of trespass; which kind of action hath now generally succeeded to the place of appeals in smaller offences not capital. 2 Hawk. c. 23.

Malicious maiming of cattle in the night time incurs a forfeiture of treble damages, by action of trespass, or upon the case, 22 & 23 Car. II. c. 7.

MAHEM, *Appeal of*. See APPEAL.

MAHLBERG, in *Geography*, a town of Baden, with an

annexed lordship; 16 miles S.S.E. of Strasburg. N. lat. 48° 19'. E. long. 7° 15'.

MAHLENDORF, a town of Silesia, in the province of Neisse; 9 miles N.W. of Neisse.

MAHMOODABAD, an ancient town of Hindoostan, formerly the capital of Guzerat, and founded by sultan Mahmood, in the 11th century. The Ayin Acbaree describes the walls of it, as including a vast extent of ground, and speaks of it, in the latter part of the 16th century, rather as an existing city, than as a place in ruins; 17 miles S.S.E. of Amedabad. N. lat. 22° 47'. E. long. 72° 52'.

MAHMORA, or MAMORA, a sea-port town of Fez, situated near the mouth of the river Seboo, which falls into the Atlantic. The fort of Mamora, which is to the south of the Seboo, is the first inhabited place in the province of Beni-hassen. It was begun by the Portuguese in 1515, and destroyed in the same year by the Moors. It was rebuilt in 1604 by the Spaniards, from whom it was taken by Muly Ishmael in 1681. This fortress, which was originally built at the mouth of the river Seboo, is now two miles distant from it, in consequence of the drifted sand-banks and bars, which have rendered the entrance of this river so difficult and dangerous, as to be no longer of any use to commerce or navigation. At this fort there are about 35 or 40 families, which gain a wretched subsistence by the profits of their ferry, and fishing for shads, of which they take such numbers as to be able to supply the whole neighbouring country between November and the end of March. Mamora is distant about five leagues N.N.E. from Sallee, and about twenty leagues by land S. of Laracha. Between these two last places the country is variegated by lakes, forests, and vallies, which were formerly tolerably populous. Some of the lakes are nearly eight leagues in extent, and supply great numbers of ducks and water-fowls, and also of eels. The boats used by the fishermen are a kind of skiffs, made of reeds and rushes, about six feet long, and two broad, and will scarcely hold a single person. The fisherman guides them with a pole, and pierces the eels when he has them on the water, with a sort of dart. On the banks of these lakes are several sanctuaries of the Maraboos, who are held in great veneration for their supposed holiness, and a number of camps of the Moors, who cultivate the adjacent lands, which are but moderately productive. This valley is very pleasant in winter and spring, but in summer it is parched and disagreeable. At the southern extremity is a sanctuary, on an eminence, appertaining to which are habitations and gardens. N. lat. 34° 25'. W. long. 6° 25'.

MAHMOUD, in *Biography*, first sultan of the Gaznevide dynasty, and a great conqueror, was son of the governor of Chorasan, and sovereign of Gazna. He was sixteen years of age when his father died in 997, and soon displayed a vigour of mind which announced his future greatness. Having secured himself upon the throne of Gazna, he marched to Chorasan, which had been seized by the king of Turkestan, drove him out, and took possession of the province. In 1001, this heroic prince carried his arms into Hindoostan, and captured Gebal, a powerful prince in that country, who, in consequence, resigned his crown to his son, and threw himself into the flames. In the following year, Mahmood reduced Khalif, the revolted governor of Segestan, and assumed the title of sultan. He repeated his invasion of India, but was soon recalled by the irruption of Ilek Khan, king of Turkestan, into Chorasan. Ilek was soon expelled; but he called to his assistance Kader Khan, who joined him with 50,000 horse. This combined and very powerful army advanced to the city of Balk, where they were met by Mahmood,

Mahmoud, when a battle ensued, which was fought with great obstinacy, but Mahmoud was victorious, and the greatest part of the Turkish army perished on the field. Mahmoud now extended his conquests far and wide, and acquired immense treasures. The emperor of Hindoostan, who had till now assumed the title of king of kings, dreading his arms, sent to demand peace from him, which was granted, on the condition of the payment of a large tribute. In 1029, he added to his other extensive dominions the great province of Persian Irak, and settled his son Massoud, whom he destined for his successor. He died in 1030, after a prosperous reign of thirty-one years. This great conqueror, who stripped to many neighbouring sovereigns of their territories, is extolled by Mahometan writers for his regard to justice, and for his zeal in the propagation of his religion, which he spread in India by the extermination of a vast number of idolaters, and the demolition of their temples. Several anecdotes are given of him which do honour to his forbearance, and his regard to justice. In one instance a widow preferred a complaint against some persons who had murdered her son; the sultan replied, that the great distance of Irak from Gazna rendered it very difficult for him to prevent such disorders: "Why then," said the disconsolate woman, "do you conquer more territory than you can govern, and of which you can render no account at the day of judgment." The reproof awakened such impressions in the mind of the monarch, that he caused it to be proclaimed throughout Irak, that he would be responsible for the lives and properties of all who should, in future, travel thence to India in caravans. Univer. Hist.

MAHMUDPOUR, in *Geography*, a town of Bengal; 14 miles S. of Boglipour.—Also, a town of Bengal, capital of the circar of Boofnah; 84 miles S.E. of Moorshedabad. N. lat. 23° 35'. E. long. 89° 42'.

MAHMUDSHI, a circar of Bengal, bounded on the N.E. and S. by Boofnah, on the W. by Shahjole, and on the N.W. by Ranjeshy, about 35 miles long, and 22 broad. Its capital is Nuldinjah.

MAHOGANY. See SWIETENIA.

MAHOMDY, in *Geography*, a town of Hindoostan, in the country of Oude; 70 miles N.W. of Lucknow. N. lat. 27° 54'. E. long. 80° 32'.

MAHOMEDABAD, a town of Hindoostan, in Oude; 13 miles E. of Azimgur.

MAHOMET, or MOHAMMED, in *Biography*, the founder of that system of religious imposture which is called *Mahometanism* (which see), descended from the tribe of Koreish, and the family of Hashem, the most illustrious of the Arabs, the princes of Mecca, and the hereditary guardians of the Caaba: he was the grandson of *Abdalmotaleb* (which see), and the only son of *Abdallah* (which see), and Amina; and he was born at Mecca, four months after the death of Justinian, and two months after the defeat of the Abyssinians, whose victory would have introduced into the Caaba the religion of the Christians, in the year 569 of the Christian era. As he was deprived of his grandfather, father, and mother in his infancy, and his inheritance consisted only of five camels and one Ethiopian female slave, the care and conduct of his youth devolved upon Abu Taleb, the most respectable of his uncles, by whom he was initiated in the occupation of a merchant, and with this view he was taken with him into Syria at the age of thirteen years. In his 25th year he was recommended to Khadijah, a noble and rich widow, as her factor, who soon rewarded his fidelity

with the gift of her hand and fortune, and thus raised him to an equality with the richest persons in Mecca. In his marriage contract he is described as the most accomplished of the tribe of Koreish, and his dowry is stipulated at twelve ounces of gold and twenty camels, which was supplied by the liberality of his uncle. In consequence of this connection, he was restored to the station of his ancestors; and he passed many years in the habits of domestic life, until at length, in the 40th year of his age, he assumed the title of a prophet, and proclaimed the religion of the Koran. According to the tradition of his companions, Mahomet was distinguished by the graces of his person and manners, so that before he spoke he engaged in attachment and interest the affections of a public or private audience. His attendants applauded his commanding presence, his majestic aspect, his piercing eye, his gracious smile, his flowing beard, his countenance that painted every sensation of the soul, and each gesture that enforced every expression of his tongue. In the intercourse of private life he blended, with respectful attention to the affluent and powerful, condescension and affability to the poorest citizens of Mecca; the frankness of his manner concealed the artifice of his views; and the habits of courtesy were imputed to personal friendship or personal benevolence. His memory was capacious and retentive; his wit easy and social; his imagination sublime; his judgment clear, rapid, and decisive. He possessed, says one of his biographers, the courage both of thought and action; and although his designs might probably expand with his success, the first idea which he entertained of his divine mission bears the stamp of an original and superior genius. Educated amidst the noblest race, he acquired a fluency of speech in the purest dialect of Arabia; and he had the art, on proper occasions, of observing a discreet silence. Notwithstanding all these accomplishments, he was an illiterate barbarian; inasmuch that his youth had never been instructed in the arts of reading and writing. Some, indeed, have questioned this fact, among whom we may reckon Mr. White (see his Sermons, p. 203, 204.); but his incredulity, founded more on conjecture and reasoning, than authentic testimony, is contradicted by numerous and unexceptionable authorities. Availing himself of the character of the age in which he lived, and of the circumstances of the people among whom his lot was cast, his sagacity led him to improve even his want of literature as a means of more successfully gaining proselytes and propagating his imposture. In his two journeys to Syria, he restricted his attention to commercial transactions at the fairs of Boltra and Damascus; and at the early age in which he made these journeys, he could derive no great advantage with regard to the purposes of his pretended mission from such hasty and superficial excursions: nor could he have indulged his curiosity to any considerable degree on account of his ignorance of the Syriac language. Whatever knowledge he acquired must have been the result of his intercourse with those pilgrims who annually resorted to Mecca from various regions, with views of devotion, or of commerce; and from this source he derived that acquaintance with the political state and character of the several Arabian tribes, as well as the theology and ceremonial institutions of Jews and Christians. Besides, from his earliest youth, Mahomet was addicted to religious contemplation; and he was accustomed, during the month of Ramadan, to retire from the world to the cave of Hera, about three miles from Mecca, where he probably formed his system of imposture; or, as Mr. Gibbon expresses it, where he consulted the spirit of fraud or enthusiasm, whose abode is not in the heavens, but in the mind of the prophet. The faith, as the historian adds, which, under the name of

"Islam," he preached to his family and nation, is compounded of an eternal truth, and a necessary fiction, "That there is only one God, and that Mahomet is the apostle of God." It is impossible, at this distance of time, and amongst the variety of opinions that have been held on the subject, to determine with certainty at what period of his life the idea of framing a new system of religion occurred to his mind; nor can it be ascertained by what kind of reflection he was led among idolaters to form his idea of the unity of God, nor to what degree he blended the ambition of personal grandeur with that of the prophetic character. History furnishes examples of persons whose conviction of truth and ardour in the prosecution and dissemination of it have terminated in the licentiousness of enthusiasm, the rage of conquest, and the violence of tyranny. Perhaps this might, in a degree, have been the case with Mahomet; and he might have proceeded from the honesty of enthusiasm to the extreme of imposture and despotism, and with a view of extending the influence of his system, he might find it necessary or expedient to accommodate it to the passions and prejudices of his countrymen, to enforce it by the terrors of the sword, and to unite the character of a conqueror with that of an impostor. It was, however, in the year 609, and about the 40th year of his age, called "the year of his mission," that he opened his pretended mission. His first convert was his wife Khadijah, to whom he communicated an interview, with which he had been favoured by the angel Gabriel, who had told him, that he was appointed the apostle of God; and to whom he also repeated a passage, which he pretended to have had revealed to him by the ministry of the angel, together with some other circumstances of this first appearance, which are related by Mahometan writers. Khadijah received the news with great joy, and hastened to impart it to her cousin Warahah, who, being a Christian, was well acquainted with the Scriptures, and who immediately became a profelyte. Cautious in announcing to the public the high and honourable office with which he was entrusted, he determined to strengthen his interest by the conversion of the other branches of his family. His next profelyte was Zeid, a confidential servant, to whom on this occasion he gave his freedom; and this circumstance established a precedent for his followers. The conversion of Zeid was succeeded by that of his cousin Ali, the son of Abu Taleb, who has been commonly styled, probably on account of his rank and zeal in the cause, "the first of believers." But the principal accession to his cause, with regard to respectability and influence, was that of Abubeker, a person of great authority in the tribe of Koreish, who prevailed on ten other principal inhabitants of Mecca to follow his example. During three years Mahomet proceeded without exciting public attention; but in the fourth year of his mission, he openly assumed the prophetic office, and announced his having received a divine appointment for the illumination and conversion of his near relations. With this view he directed Ali to prepare an entertainment, and to invite the sons and descendants of Abdalmotaleb to a participation of it. When about 40 of the race of Hashem were assembled, Mahomet addressed them with the offer of happiness both in this life and in that which is to come, for which he pleaded a divine authority and command: and he then asked them who would be his companion and vizir? Whilst a general silence prevailed, Ali exclaimed, "O Prophet, I am the man: I will be thy vizir; and I will inflict vengeance on those who oppose thee!" Upon this declaration of attachment and furious zeal in his service, Mahomet commanded all that were present to obey Ali as his deputy: the company, however, treated the order with contempt,

and ironically exhorted Abu Taleb to respect the superior dignity of his son. In a more serious tone, the father of Ali advised him to abandon his impracticable, romantic, and dangerous design. Mahomet, however, was not intimidated, but resolutely told his uncle, "that if they set the sun against him on his right hand, and the moon on his left, he would not relinquish his enterprise." When Abu Taleb perceived that he was determined to proceed, he used no further arguments to dissuade him, but promised to stand by him against all his enemies. The Koreish, finding that reasoning and intreaty were ineffectual, had recourse to threats and violence; so that the followers of Mahomet could not continue any longer at Mecca with safety; upon which Mahomet, unable to protect them, gave them leave to depart and seek refuge wherever they could find it. Accordingly, in the fifth year of the prophet's mission, sixteen, of whom four were women, fled into Ethiopia; and these were afterwards followed by others, amounting to the number of 83 men and 18 women, besides children. The king of Ethiopia received them with kindness, and refused to deliver them up when the Koreish sent to demand them; and, as the Arab writers unanimously attest, became himself a profelyte to the Mahometan religion. Persecution, instead of retarding, accelerated the progress of this imposture. In the seventh year of the mission of the pretended prophet, his friends had become more numerous and powerful, by the conversion of his uncle Hamza, and of the inflexible Omar, who had been once his most violent opposer; and the Koreish having formed a league against the Hashemites occasioned a division of their tribe into two factions; one of which adhered to the prophet and the other combined against him. For three years this variance continued, but in the tenth year of his mission, Mahomet told his uncle Abu Taleb, that God had signally manifested his disapprobation of the league, which the Koreish had formed against them, by sending a worm to eat every word of the instrument, except the name of God. When a deputation had examined the league, that had been laid up in the Caaba, and found that Mahomet's declaration was true, it was declared void. In this year Mahomet lost two very important and useful friends, viz. his wife Khadijah, and his uncle Abu Taleb; and for this reason this year was called "the year of mourning." Upon the death of these two persons the Koreishites became more violent than ever, and determined on the death of the prophet; but being warned of their purpose by an angel or spy, he retired hastily, and in the dead of the night, with his friend Abubeker, to the distance of a league from Mecca, where he concealed himself for three days in the cave of Thor, and where he and his friend received a supply of food and of intelligence from the son and daughter of Abubeker. The Koreish made diligent search for the fugitives, but being at the entrance of the cavern in which they were hidden, their attention was diverted, as it is said, by a spider's web, and a pigeon's nest, which led them to imagine that the place was solitary and inviolate. "We are only two," said the trembling Abubeker: "there is a third," replied the prophet, "it is God himself." As soon as they had opportunity for escape, they mounted their camels; but on the road to Medina, they were overtaken by the emissaries of the Koreish, from whose hands they rescued themselves by the influence of prayers and promises. The flight of the prophet from Mecca to Medina has fixed the memorable era of the *Higra*, which see. At Medina the two fugitives found an asylum. Some of the noblest citizens had previously, in a pilgrimage to the Caaba at Mecca, been converted by the preaching of Mahomet, and on their return they had diffused the belief of God and his prophet; and the new alliance was ratified by their depu-

ties in two secret and nocturnal interviews on a hill called Al Akaba, in the suburbs of Mecca, when they protested in the name of their wives, children, and absent brethren, that they would for ever profess the creed, and observe the precepts of the Koran. The second was a political association, the first vital spark, says Gibbon, of the empire of the Saracens. Seventy-three men and two women of Medina held a solemn conference with Mahomet, his kinsmen, and disciples, in the thirteenth year of his mission, and pledged themselves to each other by an oath of mutual fidelity. After reciprocal engagements to each other, they reiterated the oath of allegiance and fidelity, and their treaty was ratified by the people, who unanimously embraced the profession of Islam. Such were their circumstances, when they impatiently expected the arrival of the prophet, at the same time trembling for his safety. After a perilous and rapid journey along the sea-coast, he halted at Koba, two miles from the city, and made his public entry into Medina, 16 days after his flight from Mecca. He was met by 500 of the citizens, and received with acclamations of loyalty and devotion. His bravest disciples assembled round his person; and his followers were distinguished into two classes, the fugitives of Mecca and the auxiliaries of Medina, under the denominations of "Mohagerians" and "Ansars." When Mahomet was established at Medina, he assumed the exercise of the regal and sacerdotal office; and having acquired either by gift or purchase a piece of ground, he built upon it a temple of worship, and a residence for himself. After a reign of six years, 1500 Moslems, in arms and in the field, renewed their oath of allegiance; and their chief repeated the assurance of protection till the death of the last member; or the final dissolution of the party. Being now exalted by the choice of an independent people to the rank of a sovereign, he was invested with the prerogative of forming alliances and of waging offensive or defensive war, and accordingly assumed a fiercer and more sanguinary tone, than he had been accustomed to use, when his moderation was the effect of his weakness. In announcing his revelations, he pretended to have received commands for propagating his religion by the sword, for destroying the monuments of idolatry, and with regard to the sanctity of days or months, for pursuing the unbelieving nations of the earth. In the first months of his reign, he trained his followers for the warfare to which he intended to conduct them, and displayed his white banner before the walls of Medina, but in the progress of his undertaking he fought in person at nine battles or sieges; and fifty military enterprises were achieved in ten years by himself or his lieutenants. Uniting the professions of a merchant and robber, his petty excursions for the attack of a caravan, gradually prepared his troops for the conquest of Arabia. The distribution of the spoil was regulated, as he pretended, by a divine law; a fifth of the gold and silver, the prisoners, and the cattle, the moveables and immoveables, was reserved by the prophet for pious and charitable uses: the remainder was shared in adequate portions by the soldiers who had obtained the victory or guarded the camp; the recompense of the slain devolved to their widows and orphans; and the increase of cavalry was encouraged by the allotment of a double share to the horse and the man. From all sides, says the historian, the roving Arabs were allured to the standard of religion and plunder; the prophet indulged the disposition of his countrymen by sanctifying the licence of embracing the female captives as their wives or concubines; and the enjoyment of wealth and beauty was a feeble type of the joys of paradise prepared for the valiant martyrs of the faith. "The sword," says Mahomet, "is the key of heaven and of hell;

a drop of blood shed in the cause of God, a night spent in arms, is of more avail than two months of fasting or prayer; whoever falls in battle, his sins are forgiven: at the day of judgment, his wounds shall be resplendent as vermilion, and odoriferous as musk; and the loss of his limbs shall be supplied by the wings of angels and cherubim." By such declarations and prospects, the intrepid souls of the Arabs were fired with enthusiasm; the picture of the invisible world was strongly painted on their imagination; and the death which they had always despised, became an object of hope and desire. The prophet, with a sagacity which distinguished every part of his project, inculcated in the Koran the tenets of fate and predestination, which have served in every age to exalt the courage of the Saracens and Turks. The first companions of Mahomet advanced to battle with a fearless confidence; where there is no chance, there is no danger: they were ordained to perish in their beds, or they were safe and invulnerable amidst the darts of the enemy.

The first military expedition of any importance, and which in the event served to establish the reputation of the prophet, was directed against the Koreish. This was the battle of Beder, which was fought in the second year of the Hegira; for an account of which, see BÉDR. This was followed by a second battle, A. D. 623, on mount Ohud, six miles to the north of Medina. On this occasion the Koreish mustered a force of 3000 men, 700 of whom were armed with cuirasses, and 200 mounted on horseback. Three thousand camels attended their march; and Henda, the wife of Abu Sophian, the chief of the branch of Omniyah, who had succeeded to the principality of the republic of Mecca, with 15 matrons of this city, incessantly founded their timbrels to animate the troops, and to magnify the greatness of Hobal, the most popular deity of Caaba. The standard of God and Mahomet was upheld by only 950 believers. The Koreish advanced in the form of a crescent, and the right wing of the cavalry was led by Caled, the fiercest and the most successful of the Arabian warriors. The troops of Mahomet were skilfully posted on the declivity of a hill; and their rear was guarded by a detachment of 50 archers. The contest was vigorously maintained on both sides: it was severe and sanguinary; Mahomet was wounded, and 70 martyrs, as they were called, are said to have died for the sins of the people. Their bodies were mangled by the inhuman females of Mecca; and the wife of Abu Sophian tasted the entrails of Hamza, the uncle of Mahomet. The Mussulmans rallied in the field; and the Koreish wanted strength and courage to undertake the siege of Medina. In the year 625 the city was attacked by an army of 10,000 enemies; and this third expedition is named from the "nations" which marched under the banner of Abu Sophian, and from the "ditch" which was drawn before the city and a camp of 3000 Mussulmans, the battle of the "Nations" or "Ditch." Mahomet prudently declined a general engagement; and though the contest was protracted for 20 days, the confederates were at length obliged to separate. A tempest of wind, rain, and hail, overturned their tents; private quarrels were fomented by an insidious adversary; and the Koreish, deserted by their allies, no longer hoped to subvert the throne, or to check the conquests, of their invincible exile. As soon as the "nations" had retired from the "ditch," Mahomet, without laying aside his armour, marched against the Jewish tribe of Koraidha, who had incurred his resentment by exciting and joining the war of the Koreish; and after a resistance of 25 days, they surrendered at discretion. It was in vain that they appealed to the judgment of a venerable elder; he pronounced the sentence of their death; 700 of them were dragged in chains to the market place of the city; and hav-

MAHOMET.

ing been compelled to descend alive into the grave prepared for their execution and burial, the prophet beheld the savage scene without emotion. Plunder and cruelty marked his future footsteps; and the town of Chaibar, which was the seat of the Jewish power in Arabia, and its numerous cattle, were speedily reduced. It is somewhat singular, that a hatred of the Jews, to whose Scriptures he was indebted for the best parts of his religion, formed so distinguishing a feature in the character of the Arabian prophet. Under the subsequent reign of Omar, the Jews of Chaibar were transplanted to Syria; and the caliph alleged the injunction of his dying master, that one and the true religion should be professed in his native land of Arabia. Such was the spirit of persecution and intolerance which actuated this impostor. In the year 629 Mahomet directed his march, accompanied by 1400 men, towards Mecca: his views were peaceable; 70 camels, chosen and bedecked for sacrifice, preceded the van; the sacred territory was respected, and the captives were dismissed, without ransom, to proclaim his clemency and devotion. But on his approach to the city, the Koreish opposed his progress, and he determined to attack it; but on their suing for peace, he concluded with them and with their allies a truce of 10 years, engaging to restore the fugitives of Mecca who should embrace his religion, and stipulating merely, for the ensuing year, the privilege of entering the city as a friend, and of remaining three days to accomplish the rites of the pilgrimage. After the customary sacrifice, Mahomet evacuated the city on the fourth day. The people were edified by the devotion of the prophet, who on this occasion acted the part of a crafty politician; the hostile chiefs were awed, or divided, or subdued; and both Caled and Amrou, the future conquerors of Syria and Egypt, most seasonably deserted the sinking cause of idolatry. The Arabian tribes submitted and thus increased the power of Mahomet; 10,000 soldiers assembled for the conquest of Mecca, and the idolaters, being the weaker party, were easily convicted of violating the truce. The secret was preserved till 10,000 fires proclaimed to the astonished Koreish the design, the approach, and the irresistible force of the enemy. The haughty Abu Sophian presented the keys of the city, observed that the son of Abdallah had acquired a mighty kingdom, and confessed, under the scymetar of Omar, that he was the apostle of the true God. Mahomet, instead of indulging his own passion of revenge or that of his followers, forgave the guilt, and united the factions of Mecca. His troops, in three divisions, marched into the city and took possession of it; the chiefs of the Koreish fell prostrate at his feet; the people of Mecca merited their pardon by the profession of Islam, and after an exile of seven years, the fugitive missionary was enthroned as the prince and prophet of his native country. But the 360 idols of the Caaba were ignominiously demolished: the house of God was purified and adorned; and a perpetual law was enacted, that no unbeliever should dare to set his foot on the territory of the holy city. The conquest of Mecca determined the faith and obedience of the Arabian tribes; but an obstinate remnant still adhered to the religion and liberty of their ancestors; and the war of Honain derived its appellation from the "idols," whom Mahomet had vowed to destroy, and whom the confederates of Tayef had sworn to defend. Four thousand pagans advanced with secrecy and speed to surprize the conqueror; the banners of Mecca and Medina were displayed by the prophet; and 12,000 Mussulmen entertained a rash and sinful presumption of their invincible strength. They descended without precaution into the valley of Honain; but their number was oppressed by the archers and slingers of the confederates who

had occupied the heights, their discipline was confounded, their courage was appalled, and the Koreish anticipated with satisfaction their impending destruction. The prophet, on his white mule, was encompassed by the enemies; of ten faithful companions, who attempted to ward off from him the spears of the assailants, three fell dead at his feet; and in this moment of danger, he called on his brethren and on the Almighty for succour, whilst his uncle Abbas joined in the acclamations of his followers. At length the fugitive Mussulmen rallied; the battle was renewed by the exhortation and example of the prophet; and he animated his victorious troops to inflict a merciless revenge on the authors of their disgrace. From the field of Honain he hastened to the siege of Tayef, 60 miles S.E. of Mecca; but after an ineffectual attack of 20 days, he was obliged to retreat. The spoil of this expedition amounted to 6000 captives, 24,000 camels, 40,000 sheep, and 4000 ounces of silver. Instead of chastising the disaffection of the Koreish, he endeavoured to secure their attachment by extraordinary liberality; Abu Sophian was presented with 300 camels and 20 ounces of silver; and Mecca was sincerely converted to the profitable religion of the Koran. The temples and idols of Arabia were every where demolished, and the ambassadors who prostrated themselves before the throne of Medina were as numerous, according to an Arabian proverb, as the dates that fall from the maturity of a palm-tree. Hence this year was called "the year of embassies." The nation submitted to the God and the sceptre of Mahomet; and 114,000 Moslems accompanied the last pilgrimage of the apostle. On this occasion he took with him all his wives, with a great number of camels intended for victims; and the ceremonial which he observed at the sacred city has served as a model to the Moslems of succeeding ages.

It was in the 7th year of the Hegira that Mahomet began to think of propagating his religion beyond the boundaries of Arabia, and deputed messengers to invite the neighbouring princes to embrace Mahometanism. The Persians with their sovereign after some hesitation avowed themselves proselytes. The emperor Heraclius at first treated his message with respect; and some have said, that he would have professed the new faith, if he had not been afraid of losing his crown. Mahomet prepared for effecting by conquest what he had failed to accomplish by a peaceful message; but he was obliged to desist from the undertaking, as too hazardous, and indeed impracticable. The first conflict between the troops of Mahomet and the emperor Heraclius took place in the eighth year of the Hegira. A body under the command of Zeid advanced to the attack of Muta, a town of Palestine, the governor of which had assassinated one of the Moslem envoy. In the sharp conflict that ensued, Zeid with the two next in command was slain, and the death of Zeid was much lamented by Mahomet, his master and friend. However, the active and intrepid Caled, denominated "the Sword of God" spread around the terror of his name: and the prophet received the submission of the tribes and cities from the Euphrates to Ailah, at the head of the Red sea. Mahomet, in the confidence of his power, had declared war against Heraclius; and with an army of 20,000 foot and 10,000 horse, he marched towards the Syrian frontier, and his unwilling followers suffered extremely from the heat of the summer and the drought of the desert. At Tabuc, a fertile spot in the midway between Medina and Damascus, they pitched their camp. The consequence of this toilsome expedition was the submission of some Arabian princes, who became tributaries; but as the Imperialists had retired to a distance, without appearing to have any design of making an attack upon Arabia, Mahomet satisfied himself by writ-

MAHOMET.

ing a letter to Heraclius urging his conversion, and then returned back to Medina. After his return he promulgated a new chapter of the Koran, revoking all former edicts in favour of the idolaters, and annulling all treaties that had been made with them. To his Christian subjects, Mahomet readily granted the security of their persons, the freedom of their trade, the property of their goods, and the toleration of their worship. In this respect he pursued a conduct highly political, as it was the interest of a conqueror to propose a fair capitulation to the most powerful religion of the earth: and the same wise policy has ever since accompanied the Mahometan jurisdiction. Till the age of 63 years, Mahomet retained a vigour of constitution which enabled him to endure the corporeal and spiritual fatigues of his mission. The last conspicuous act of his life was his pilgrimage to Mecca, already mentioned. His health had been declining for four years previous to his death; and he ascribed this change not to the access of epileptic fits which some writers have erroneously reported to have been the remote cause of his growing infirmities, but to poison administered to him at Chabar by a Jewish female, from a motive of revenge, as some have said, or according to others, from a desire of putting his prophetic character to the test. However this be, his mortal disease was a fever of fourteen days, which at intervals deprived him of the use of his reason. During the intermissions of his disorder he employed himself in haranguing his disciples from the pulpit, and performing other religious duties of his function, and in giving instructions with regard to the measures that were fit to be pursued after his decease. He beheld, it is said, with firmness the approach of death, satisfied the demands of his creditors, enfranchised his slaves, directed the order of his funeral, moderated the grief of his weeping friends, on whom he bestowed the benediction of peace, and regularly performed the exercise of public prayer till the third day before his dissolution; from all which circumstances it has been inferred, that he really believed the truth of his mission, and that he derived consolation from the consciousness of having conferred great benefits on mankind. This may be easily accounted for by the consideration that enthusiasm was blended in a very considerable degree with his imposture. The choice of Abubeker to supply his place indicated his respect for this ancient and faithful friend, as he seems to have thought him a fit successor in the sacerdotal and regal office. When his faculties were perceptibly impaired he wished to dictate a divine book, which should contain the form and substance of all his revelations; but a dispute arising in his chamber, whether he should be allowed to supersede the authority of the Koran, he was under a necessity of reproving the indecent vehemence of his disciples. If any credit may be given to the traditions of his wives and companions, he maintained to the last moments of his life and in confidential intercourse with his family, the dignity of an apostle and the faith of an enthusiast; describing the visits of Gabriel, and expressing his lively confidence, not only in the mercy, but the favour, of the Supreme Being. In a familiar discourse he had mentioned his special prerogative, That the angel of death was not allowed to take his soul till he had respectfully asked the permission of the prophet. The request being granted, Mahomet fell into the agony of dissolution, and expired in the arms or on a carpet near the feet of his favourite wife Ayesha, the daughter of Abubeker, in the month of June, A.D. 632, Hegira 11, at the age of 63. Some of his followers would not for a time believe the reality or possibility of his death, till Abubeker calmly reasoned them out of their delusion. He was interred at Medina, in a grave dug beneath the bed

on which he lay in the apartment of Ayesha, over which a magnificent building was erected by one of the succeeding caliphs. It is hardly necessary to mention, unless with a view of exposing it, the vulgar and ridiculous story invented and propagated by the Greeks and Latins, that Mahomet's tomb is suspended in the air at Mecca, by the action of equal and potent load-stones: for he was not buried at Mecca, and his tomb at Medina, which has been visited by millions, is placed on the ground. The number of his wives, all of whom except Ayesha were widows, was at least fifteen: by Khadijah he had four children, one of whom, Fatima, the best beloved of his daughters, and married to Ali, survived him; and he had also a son, by his Egyptian concubine, Mary, whose name was Ibrahim, and who died not long before him. However Mahomet might restrict the incontinence of his disciples by the precepts of his religion, he claimed a special exemption for himself, and pretended a special revelation which dispensed with his observance of the laws which he imposed upon his nation. During the life of Khadijah, who laid the foundation of his future fortune, and in the course of 24 years, he seems to have restrained his ruling passion within due bounds; but as he advanced in years and authority, this passion gained strength, and he made his religion subservient to the illicit indulgence of it. Besides his numerous wives, he allowed himself in a variety of amours, which were prohibited by his own laws. His connection with Zeinah, the wife of his enfranchised servant and adopted son, Zeid, gave great offence to some of his friends. Zeid, in order to gratify his master, consented to her being divorced; and the prophet, whose religion was easily accommodated to his passions and interest, feigned a revelation from heaven, recorded in a chapter of the Koran, which authorized him to marry her, notwithstanding a degree of affinity that had been always regarded by the Arabs as an absolute prohibition. Hafsa, the daughter of Omar, who was one of his wives, discovered him in an improper situation with Mary, an Egyptian captive; but in order to silence her reproaches, he promised never to repeat the offence. Finding, however, that the circumstance was divulged to his other wives, and that they concurred in resenting it, he withdrew from them all for a month, and spent the time in company with Mary; and in order to justify his infidelity and violation of an oath, he recurred to his usual practice of producing a new chapter of the Koran, containing a special dispensation. We may indeed be astonished that successive forgeries of this kind, intended to answer purposes of personal and licentious gratification, should not have excited a prejudice in the minds of his followers and of his countrymen in general, which would have defeated all his efforts for propagating his imposture. But we should recollect the disposition and character of the Arabs, whose libidinous complexion has been noticed by the writers of antiquity. (Ammian Marcell. l. xiv. c. 4.) Much has been said by Mahometan writers in praise of the corporeal and mental endowments of the Arabian prophet; and though we cannot allow the very extraordinary qualities which have been ascribed to him, it must be acknowledged that he possessed various accomplishments, some of which have already been noticed, and a versatility of talents and character, that served to raise him above his contemporaries, and to qualify him for the undertaking in which he embarked. "Could I truly delineate," says Gibbon, "the portrait of an hero, the fleeting resemblance would not equally apply to the solitary of mount Hera, to the preacher of Mecca, and to the conqueror of Arabia. The author of a mighty revolution appears to have been endowed with a pious and contemplative disposition: so soon as marriage had

had raised him above the pressure of want, he avoided the paths of ambition and avarice; and till the age of 40, he lived with innocence, and would have died without a name. The unity of God is an idea most congenial to nature and reason; and a slight conversation with the Jews and Christians would teach him to despise and detest the idolatry of Mecca." Indeed, for every thing that is valuable in his religious system he was indebted to Judaism and Christianity; but his rude and barbarous civil policy, being rendered immutable by its alliance with religion, an alliance that is incongruous and unnatural, has prevented every kind of melioration and improvement in those countries where his laws are received. "It was the duty of a man and a citizen to rescue his country from sin and error. The energy of a mind incessantly bent on the same object would convert a general obligation into a particular call; the warm suggestions of the understanding or the fancy would be felt as the inspirations of heaven; the labour of thought would expire in rapture and vision; and the inward sensation, the invisible monitor, would be described with the form and attributes of an angel of God. From enthusiasm to imposture the step is perilous and slippery: the *dæmon* of Socrates (see *DÆMON*) affords a memorable instance how a wife man may deceive himself, how a good man may deceive others, how the conscience may slumber in a mixed and middle state between self-illusion and voluntary fraud. Charity may believe that the original motions of Mahomet were those of pure and genuine benevolence; but a human missionary is incapable of cherishing the obstinate unbelievers who reject his claims, despise his arguments, and persecute his life;"—hence "the passions of pride and revenge were kindled in the bosom of Mahomet."—"The injustice of Mecca, and the choice of Medina, transformed the citizen into a prince, the humble preacher into the leader of armies."—"In the exercise of political government, he was compelled to abate of the stern rigour of fanaticism, to comply in some measure with the prejudices and passions of his followers, and to employ even the vices of mankind as the instruments of their salvation: the use of fraud and perfidy, of cruelty and injustice, was often subservient to the propagation of the faith; and Mahomet commanded and approved the assassination of the Jews and idolaters, who had escaped from the field of battle. By the repetition of such acts, the character of Mahomet must have been gradually stained; and the influence of such pernicious habits would be poorly compensated by the practice of the personal and social virtues which are necessary to maintain the reputation of a prophet among his sectaries and friends. Of his last years, ambition was the ruling passion; and a politician will suspect, that he secretly smiled (the victorious impostor!) at the enthusiasm of his youth and the credulity of his profelytes." Mahomet, in his private and domestic life, seems to have despised the pomp of royalty, and to have submitted to the menial offices of the family. The interdiction of wine was confirmed by his example, and his ordinary food consisted of barley-bread, milk and honey, dates and water. Although he indulged himself in sensual gratifications, the incontinence of his countrymen was regulated by the civil and religious laws of the Koran: their incestuous alliances were blamed; the boundless licence of polygamy was reduced to four legitimate wives or concubines; their rights both of bed and of dowry were equitably determined; the freedom of divorce was discouraged; adultery was condemned as a capital offence; and fornication, in either sex, was punished with an hundred stripes.

It is a natural inquiry how Mahomet, without literature, without pretending to the power of working miracles, and

without a character that entitled him to veneration among persons who made any pretence to religion and virtue, secured the success of a system of doctrine and practice, which must have appeared to all but his prejudiced followers to have originated in enthusiasm and imposture?—a system which restricted the boundless licence of Arabian idolatry; which imposed obligations of prayer, purification, and almsgiving, that were burthensome; and which undermined the interest and influence of some of the most powerful and affluent of his countrymen? The basis of his doctrine, we have already said, was the truth of the unity and spiritual nature of the deity: this truth must have approved itself to the minds of the thoughtful; and the vulgar would be allured by the prospects which he held out to them of a future happiness, adapted to their grosser apprehensions and passions. Whilst we admit that, in the early period of his pretended mission, he might have been actuated by a sincere desire of ameliorating the faith and manners of his countrymen, and allow his character to have possessed some traits of the patriot and reformer, pride and ambition were his ruling principles; and his discriminating character must be that of an usurper and impostor, who owed his success more to the accommodating nature of his doctrine, and to the power of the sword, than to any other cause. "Are we surprised," says Mr. Gibbon, "that a multitude of profelytes should embrace the doctrine and the passions of an eloquent fanatic? In the heresies of the church, the same seduction has been tried and repeated from the time of the apostles to that of the reformers. Does it seem incredible that a private citizen should grasp the sword and the sceptre, subdue his native country, and erect a monarchy by his victorious arms? In the moving picture of the dynasties of the last one hundred fortunate usurpers, none have arisen from a baser origin, surmounted more formidable obstacles, and filled a larger scope of empire and conquest. Mahomet was alike instructed to preach and to fight; and the union of these opposite qualities, while it enhanced his merit, contributed to his success: the operation of force and persuasion, of enthusiasm and fear, continually acted on each other, till every barrier yielded to their irresistible power. His voice invited the Arabs to freedom and victory, to arms and rapine, to the indulgence of their darling passions in this world and the other. The restraints which he imposed were requisite to establish the credit of the prophet, and to exercise the obedience of the people: and the only objection to his success was his rational creed of the unity and perfections of God. It is not the propagation, but the permanency of his religion that deserves our wonder: the same pure and perfect impression, which he engraved at Mecca and Medina, is preserved, after the revolutions of 12 centuries, by the Indian, the African, and the Turkish profelytes of the Koran."—"The Turkish dome of St. Sophia, with an increase of splendour and size, represents the humble tabernacle erected at Medina by the hands of Mahomet. The Mahometans have uniformly withstood the temptation of reducing the object of their faith and devotion to a level with the senses and imagination of man. "I believe in one God, and Mahomet the apostle of God," is the simple and invariable profession of Islam. The intellectual image of the Deity has never been degraded by any visible idol, &c. "From the Atlantic to the Ganges, the Koran is acknowledged as the fundamental code, not only of theology but of civil and criminal jurisprudence; and the laws which regulate the actions and the property of mankind are guarded by the infallible and immutable sanction of the will of God."

In a review of the causes which seem to have facilitated the original success of Mahometanism, professor White

(Sermons,

MAHOMET.

(Sermons, ii.) traces them in the scandalous divisions and deplorable corruptions of the Christian church; in the political and religious state of Arabia; in the independence and want of union among its tribes; in the gross ignorance (particularly with regard to religion) of its barbarous and uncivilized inhabitants; and, lastly, in the nature and genius of Mahometanism itself; in the fascinating allurements of its promised rewards, in their agreeableness to the propensities of corrupt nature in general, and to those of the inhabitants of warmer climates in particular; in the artful accommodation of its doctrines and its rites to the preconceived opinions, the favourite passions, and the deep-rooted prejudices of those to whom it was addressed; in the poetic elegance with which its doctrines, its precepts, and its histories were adorned, and in the captivating manner in which they were delivered. As the corrupt and distracted state of the Christian church had originally assisted the rise, so did it operate with still greater force in favour of the subsequent progress of Mahometan imposture. If, indeed, we allow to this cause its proper influence; if we consider the weakness of the surrounding nations, and the natural strength of Arabia, now collected and pointed to one object; if we reflect on that fervour of zeal, and that wildness of enthusiasm, which were now superadded to the native valour of a hardy and warlike people; we shall cease to wonder at the victories and triumphs they obtained over the lukewarm and degenerate defenders of the gospel. Of these victories and these triumphs, the propagation of their new faith was the professed object and design: thus, by violence and bloodshed had the prophet himself finally established his religion among his countrymen; and thus had he expressly commanded his followers to extend it over all the regions of the earth. Of the continuance of Mahometanism, when thus established, and of its existence to the present times, various causes might be assigned, whose joint operation would be sufficient to account fully for the effect, without having recourse to any miraculous or particular interposition of providence. Of these causes we shall satisfy ourselves with mentioning only one, which appears to be of peculiar force and importance. In almost all those countries, which acknowledge the authority of Mahomet, so intimate is the connection, so absolute the dependence of the civil government on religion, that any change in the latter must necessarily and inevitably involve the ruin and overthrow of the former. The Koran is not, like the gospel, to be considered merely as the standard by which the religious opinions, the worship, and the practice of its followers are regulated; but it is a political system; on this foundation the throne itself is erected; from hence every law of the state is derived; and by this authority every question of life and of property is finally decided. It is obvious, therefore, that in every country where Mahometanism had been once received and established, the circumstance now mentioned must have operated with uncommon weight to crush any important innovation in religion; since from this inseparable connection between the sanctions of religion and those of the state, every such innovation would be considered in no other light, than as an attempt to overturn the civil government, to loosen the bands of society, and to destroy every privilege of law, and every security of property.

Mahomet was succeeded by Abubeker, agreeably to the wishes of the deceased prophet; who, after a reign of two years, was followed by Omar; and in the 12th year of his government, he received a mortal wound from the hand of an assassin, and made way for the succession of Othman, the secretary of Mahomet. After the third Caliph, 24 years after the death of the prophet, Ali was invited, by the

popular choice, with the regal and sacerdotal office. Among the numerous biographers of Mahomet, we may reckon Abulfeda, Maracci, Savary, Sale, Prideaux, Boulainvilliers, D'Herbelot, Gagnier, Gibbon, and the author of the article in the Modern Universal History. See *ALCORAN* and *MAHOMETANISM*.

MAHOMET I., sultan of the Turks, born about the year 1374, was one of the sons of Bajazet, who was dethroned by Tamerlane. After his brother Solyman had lost his life in the war with Mufa, he declared himself his avenger, and being assisted by the Greek emperor Manuel, defeated Mufa, who was killed in the field, or made captive and put to death by Mahomet's orders. The victor was proclaimed sultan at Adrianople in 1413, which city he made the seat of his empire. Soon after his accession, he passed over with an army into Lesser Asia, and did much mischief there. After having subdued Servia, part of Sclavonia, and Macedonia, and reduced to obedience the provinces of Lesser Asia, he died in the year 1421, having reigned eight years with discretion and success, and leaving behind him a character respectable for justice and clemency. *Univer. Hist. Gibbon.*

MAHOMET II., emperor of the Turks, named "The Great," and "The Victorious," son of sultan Amurath, or Morad II., was born at Adrianople in 1430, and received an education very superior to that generally bestowed on the princes of the Turkish empire. He was well skilled in five languages, and was conversant in history and geography. During the life of his father, he twice assumed the sovereignty, and twice relinquished it, at the command of his parent. He made no opposition to his father's will, but never forgave the ministers who were the advisers of the measure. One of his first acts, after the death of his father, was the siege of Constantinople, which commenced in the spring of 1453; he caused cannon of a prodigious size to be cast, and assembled a vast army from all parts of his dominions, with a great fleet. He superintended the operations himself, and by a severity that punished the smallest disobedience with death, and the most magnificent promises of reward, he stimulated the exertions of his troops. The vast disparity of force between the assailants and defenders, leaves little room for admiring the military skill and prowess of the victorious party. The sultan, resolved to carry his point, let it cost what it would, drove on his men to the attack, and it was by numbers that the final success was obtained. (See *CONSTANTINOPLE*.) It was on the twenty-ninth of May 1453, that the general assault was made which determined the fate of that city. After a gallant resistance with his few faithful followers, the last Greek emperor lost his life in the press, and the Turks burst into the city through the breaches of the walls. Mahomet filled his victory by the most brutal conduct, but as he determined to fix the seat of his empire in this admirable situation, he repaired and repopled the city partly from his own subjects, and partly from the fugitive Greeks; to whom he allowed the free exercise of their religion. The great church of Santa Sophia was converted into a mosque, and the crescent took place of the cross, in this second capital of Christendom. After the event, the western writers give Mahomet the title of emperor of the Turks. Almost the whole reign of this monarch was spent in martial projects, which rendered him equally the terror of the Christian world, and the pride of the Mahometan. His conquests were very numerous: he invaded Servia, and made it tributary; he took Mitylene, the ancient Lesbos, with the other islands, and reduced Bosnia under his dominion, which, however, was afterwards recovered by Matthias, king of Hungary.

He subdued Caramania, the sovereigns of which had long been the most inveterate enemies of the Turkish sultans. He conquered Negropont, the ancient Eubœa, and wrested Kassa in Crim Tartary from the Genoese. One of his latest attempts was the siege of Rhodes, in which he was rendered unsuccessful by the valour of the knights. He, however, as a compensation for this disaster, captured Otranto in Italy, which gave him a footing in that country; but to him this was of little use; his end was hastily approaching; he died in the month of May 1481, at the age of fifty-one, after a reign of thirty years. The vigour of mind and body, and the loftiness of enterprize by which this conqueror was characterized, raise him vastly above the mere possessors of an hereditary throne. His successes, however, were chiefly obtained by the force of numbers, urged on by an unfeeling despotism, and it has been asserted that he generally failed in the contest with combined skill and valour. The evils which he brought upon Christendom have caused his moral qualities to be painted in the darkest colours by its writers. He has been accused of irreligion, perhaps chiefly from the tolerant spirit which directed his conduct towards the vanquished of different religions; yet he displayed the usual zeal of princes in founding splendid edifices for the public worship of the established faith. Univer. Hist. Gibbon.

MAHOMET III., emperor of the Turks, son of Amurath III., was born in 1564, and succeeded to the throne on the death of his father in 1596. The first act of his infamous reign was the murder of nineteen brothers, and of ten of his father's wives from whom offspring might be apprehended. Having thus secured his throne, he gave himself up to indolence and sensuality, little attentive to the affairs of the empire, which were seldom more unprosperous than in this reign. In his contests with neighbouring powers he was commonly unsuccessful. A series of disasters excited against him a conspiracy, to quell which, he was under the necessity of sacrificing some of his officers, and banishing the queen mother from his counsels. Mahomet died in 1603, at the age of thirty-nine, after an inglorious reign of about eight years.

MAHOMET IV., emperor of the Turks, was born in 1642, and succeeded his deposed father Ibrahim in 1649. During his minority the government was administered by his mother, assisted by a council of bashaws. He found his country at war with the Venetians, which was continued with various success. The empire at home was convulsed by the revolt of the bashaw of Aleppo, who at first gained great advantages over the grand vizier, but in the end lost his life. In the year 1665, war was rekindled with great vigour in Hungary, and the Turkish arms were at first successful. A great victory gained by Montecuculi, the imperial general at Raab, in 1664, inclined the Ottoman court to a peace, which was soon after concluded. The conquest of the island of Candia from the Venetians in 1669, after a siege of 25 years, was one of the most memorable events of this reign. A war with Poland in 1672, was terminated with a peace very humiliating to the Poles, but the nation refused to ratify it, and John Sobieski in the following year gave the Turks a complete defeat at Choczim, which circumstance was the means of raising him to the Polish throne. After this, for several years, the tide set in strongly against the Turks. A career of ill fortune excited discontents among them, and the army broke out into a fierce mutiny. Quitting their camp near Belgrade, they marched for Constantinople, and sent before them a demand of the grand vizier's head; which was granted. They next upbraided the sultan with his neglect of public affairs, and entreated him to resign a government which he had proved himself unfit

to conduct. Mahomet, as a measure of self-defence, determined to put his brothers to death, but being apprised of his intention, they took methods of saving themselves from the threatened danger. At length Mahomet submitted to pronounce the decree of his own resignation. He quitted the throne in 1687, and was confined to his apartment, where he survived till the year 1691. He left two sons, who afterwards came to the throne of the empire. Mahomet IV. is described as distinguished for justice, clemency, and valour, though the history of his reign is that of his generals and ministers; his own activity was shewn chiefly, if not wholly, in the pursuits of the chase. Univer. Hist.

MAHOMET Pigeon, in Ornithology, the common English name of a species of pigeon, called by Moore the *columba Numidica alba*. It is of the same shape and size with the Barbary pigeon, and has all the characters of that species, but is always perfectly white, which gives the red circle about the eyes a more lively look. See COLUMBA.

MAHOMETANISM, MAHOMETISM, or MOHAMMEDISM; the system of religion broached by Mahomet, and still adhered to by his followers. See MAHOMET.

Mahometanism is embraced by the Turks, Persians, and several nations among the Africans, and many among the East Indians.

Brewerwood says, that if we divide the known countries of the earth into thirty equal parts, five of them are Christians, six Mahometan, and nineteen Pagan.

The system of Mahometanism is contained in the Koran, commonly called the *Alcoran*; which see.

The first and chief article of the Mahometan creed is, that *there is no other God but one God*; which they have from the Koran, where these words are repeated incessantly: *there is no other God but he. Your God is the only God. I am God, and there is no other God but I.* This grand axiom of their theology seems to have been taken from the Jews, who were continually rehearsing those words of Deuteronomy, *Hear, O Israel; the Lord our God is One.*

For this reason, the Mahometans account all such as own any thing of number in the divinity, to be infidels or idolaters. And accordingly, one of the first lessons they teach their children is, that God is neither male nor female, and, consequently, can have no children. (See the 2d, 57th, and 58th chapters of the Koran.) Hence, the proselytes of Mahomet, from India to Morocco, are distinguished by the name of "Unitarians;" and the danger of idolatry has been prevented by the interdiction of images.

The second article of Mahometanism consists in this, that *Mahomet was sent from God*. By which they exclude all other religions; under pretence that their prophet was the last and greatest of all the prophets that God would ever send, and that as the Jewish religion ceased with the coming of the Messiah, so likewise the Christian religion was to be abrogated with the coming of Mahomet. Not but they own Moses and Jesus Christ to have been great prophets; but Mahomet they hold to be "The Prophet," by way of excellence, commissioned to purge the holy scriptures of the Old and New Testament, which they allow, from the corruption introduced in them by Jews and Christians, and to restore the law of God to its original purity; and the paraclete or comforter promised in the scriptures.

The Mahometans call their religion *Islam*, denoting, as some say, *resignation* or *submission* to the service and commands of God; but, according to others, formed from the root *sulama*, signifying *to be saved*, and, therefore, the same with the *religion* or *state of salvation*; and they divide it into two distinct parts, *viz. imân, i. e. faith* or *theory*; and *dîn,*

MAHOMETANISM.

i. e. religion or practice : and teach that it is built on five fundamental points, one belonging to faith and the other four to practice.

Under the confession of faith already recited, they comprehend six distinct branches, viz. belief in God ; in his angels ; in his scriptures ; in his prophets ; in the resurrection and day of judgment ; and in God's absolute decree and predetermination both of good and evil. The four points relating to practice, are prayer, under which are comprehended those washings or purifications which are necessary preparations required before prayer ; alms, fasting, and the pilgrimage to Mecca. Their faith in God has been already mentioned ; with respect to their opinion of angels, they believe them to have pure and subtle bodies, created of fire, and that they are differently employed, in writing down the actions of men, or in carrying the throne of God, and other services. The four angels, whom they regard as most distinguished by God's favour, and on account of the offices assigned them, are Gabriel, called the holy spirit, and the angel of revelations, and supposed to be honoured with the peculiar confidence of God, and employed in writing down the divine decrees ; Michael, the friend and protector of the Jews ; Azrael, the angel of death, who separates men's souls from their bodies ; and Israfil, whose office it will be to found the trumpet at the resurrection. They also believe that two guardian angels, changed every day, attend on every man, to observe and write down his actions. Their whole doctrine concerning angels they have borrowed from the Jews, who learned the names and offices of those beings from the Persians. The devil, called by Mahomet " Eblis," from his despair, was one of those angels, who are nearest to God's presence, called Azazel, and fell, according to the doctrine of the Koran, for refusing to pay homage to Adam at the command of God. They also admit an intermediate order of beings, called genii, some of which are good, and others bad ; and capable of future salvation or condemnation, as men are, whence Mahomet pretended, that he was sent for the conversion of genii as well as of men.

As to the scriptures, the Mahometans are taught by the Koran, that God, in divers ages of the world, gave revelations of his will in writing to several prophets, the whole, and every word of which, it is absolutely necessary for every good Moslem to believe. Mahomet acknowledges the divine authority of the Pentateuch, Psalms, and Gospel, and often appeals to the consonancy of the Koran with those writings, and to the prophecies, which he pretended, were contained concerning himself, which the Jews and Christians have suppressed.

Besides these books, the Mahometans take notice of the writings of Daniel and several other prophets, and even cite them, but they do not believe them to be divine scripture, or of any authority in matters of religion. Among the prophets, in number 224,000 according to some, and 124,000 according to others, they reckon 313 apostles, bearing special commission to reclaim mankind from infidelity and superstition ; six of whom were entrusted with new laws or dispensations, successively abrogating the preceding : these were Adam, Noah, Abraham, Moses, Jesus, and Mahomet.

At death, they maintain, that the bodies of those, who believe the unity of God, and the mission of Mahomet, rest in peace, and are refreshed with the air of paradise ; otherwise they are grievously tormented. The souls of the former are conveyed to heaven, where a place is assigned them according to their merit and degree ; those of the wicked are tormented, till they are rejoined to their bodies

at the resurrection ; the approach of which will be known by certain signs that precede it : these are the lesser and the greater signs ; the latter of which are the sun's rising in the west ; the appearance of a monstrous beast, which shall rise out of the earth in the temple of Mecca ; war with the Greeks and the taking of Constantinople ; the coming of Anti-Christ ; the descent of Jesus on earth ; war with the Jews ; the eruption of Gog and Magog ; a smoke which shall fill the whole earth ; an eclipse of the moon ; the return of the Arabs to the worship of their ancient idols ; the discovery of a vast heap of gold and silver by the retreat of the Euphrates ; the demolition of the temple of Mecca by the Ethiopians ; the speaking of beasts and inanimate things ; the breaking out of fire in the province of Hejaz or Yemen ; the appearance of a man, who shall drive men before him with his staff ; the advent of the Mohdi, or director, a person of the family of Mahomet, to govern the Arabians, and fill the world with righteousness ; and a wind that shall sweep away the souls of all who have but a grain of faith in their hearts. But the immediate sign of the resurrection will be the first blast of the trumpet, which will be sounded three times. The day of judgment will continue, as the Koran says in one place, 1000 years, but according to another passage, 50,000 years : the resurrection, say they, will be general, extended to all creatures, angels, genii, men, and animals ; who will be assembled on the earth, give an account of their actions, and receive retribution. On this occasion each person will have the book, wherein all the actions of his life are written, delivered to him, and their works will be weighed in a balance, which they minutely describe. When the examination is finished mutual retaliation will follow ; which will be executed by taking away a proportionable part of the good works of him who offered injury to another, and adding it to him who suffered it. Brutes will be changed into dult ; and the believing genii be assigned a place near the confines of paradise, and the unbelieving punished eternally and cast into hell, with the infidels of mortal race. After this process, the good and wicked are conducted to a bridge, called Alfrat ; over which the former shall safely pass, while Mahomet and his Moslems lead the way, but the latter will fall down headlong into hell ; where there are seven different apartments, adapted to as many distinct classes of the damned, who will suffer both from intense heat and excessive cold. In this state infidels only will be liable to eternal punishment ; but the Moslems or believers will be delivered thence, after they have expiated their crimes by their sufferings. This place of punishment is separated from paradise by a wall, called " Al drat," so small in breadth as to admit the blessed and damned to converse together. The righteous, after having passed the bridge above-mentioned, will be refreshed by drinking at the pond of their prophet, and then admitted into paradise, situated in the seventh heaven, and next to the throne of God ; where they will feed on the most delicious fruits, be clothed in the most splendid silken garments, refreshed with rivers of water, wine, milk, and honey, and entertained with the most delightful music, and the ravishing girls of paradise with black eyes, the enjoyment of whose company will be a principal felicity of the faithful.

It appears from the Koran, that women as well as men will not only be punished for their evil actions, but also receive the reward of their good deeds, and that both will enjoy a perpetual youth.

Hence it appears, that the vulgar opinion, which charges the Mahometans with maintaining that women have no souls, or if they have any, that they will perish like the

MAHOMETANISM.

brutes, without any future recompence, is erroneous. It is, however, a general action, that they will not be admitted into the same abode as the men, because their places will be supplied by the paradisaical females already mentioned. One circumstance relating to these beatified females, conformable to what Mahomet had asserted of the men, he acquainted his followers with in the reply which he made to an old woman; who desiring him to intercede with God, that she might be admitted into paradise, was told by him, that no old women would enter that place; which causing the aged female to sigh and shed tears, he explained himself by saying, that God would then make her young again.

Farther, the orthodox doctrine with respect to predestination is, that every thing which happens in this world proceedeth entirely from the divine will, and is irrevocably fixed from all eternity in the preserved table; God having secretly predetermined not only the adverse and prosperous fortune of every person in this world, in the most minute particulars, but also his faith or infidelity, his obedience or disobedience, and consequently his everlasting happiness or misery after death; which fate or predestination it is not possible for any fore-sight or wisdom to avoid.

Of this doctrine Mahomet makes great use in his Koran for the advancement of his designs, encouraging his followers to fight without fear, and even desperately, for the propagation of their faith, representing to them that no caution on their part could avert their inevitable destiny, or prolong their lives for a moment.

In regard to the four fundamental points of religious practice; Mahomet is said to have declared, that the practice of religion is founded on cleanliness, which is one-half of the faith, and the key of prayer, without which it will not be heard by God. Such is the opinion which the Mahometans entertain of cleanliness, that it is purely on this account they seem to have adopted circumcision, though it be not mentioned in the Koran. Mahomet has obliged his followers to pray five times every twenty-four hours, at certain stated seasons, turning their faces towards the temple of Mecca, which is pointed to by a niche in their mosques: the life and spirit of prayer, they hold, are the inward disposition of the heart; nor do they ever perform this duty in sumptuous apparel, nor suffer their women to attend them on these occasions, lest their presence should inspire a different kind of devotion from that which is requisite in a place dedicated to the worship of God.

Aims, among the Mahometans, are legal and voluntary; the giving of which is frequently inculcated in the Koran. Hasan, or Husein, the son of Ali, and grandson of Mahomet, is said to have thrice in his life divided his substance equally between himself and the poor, and twice to have given away all he had; and the generality of Mahometans are so addicted to acts of benevolence, that they extend their charity even to brutes. Fasting is called by Mahomet the gate of religion; and his followers are expressly required to fast during the month of Ramadan; which they observe by abstaining from meat, drink, and women, from day-break till sun-set. Besides this, they have several other voluntary fasts. The pilgrimage to Mecca is so necessary a point of practice, that, according to a tradition of Mahomet, he who dies without performing it may as well die a Jew or a Christian; and it is expressly commanded in the Koran. The various ceremonies prescribed to those who perform this pilgrimage are extremely absurd and ridiculous, and appear to be relics of idolatrous superstition.

Besides the fundamental points of faith and practice above recited, the Mahometans are required by the Koran, to abstain from wine, gaming, usury, divining by arrows, the

cating of blood and swine's flesh, and whatever dies of itself, or is slain in honour of any idol, or strangled, or killed by accident, or by any other beast. The Koran allows polygamy within certain limits; forbidding any man to have more than four, whether wives or concubines: but Mahomet had the privilege of marrying as many wives, and keeping as many concubines as he pleased. It allows also of divorce; but severely punishes fornication and adultery.

Wilful murder, though forbidden by the Koran under the severest penalties to be inflicted in the next life, is nevertheless by the same book allowed to be compounded for, on payment of a fine to the family of the deceased, and freeing a Moslem from captivity; but this commutation depends on the choice of the next of kin, who may either accept or refuse it. Manslaughter was redeemed by fine, and the freeing of a captive; and if a man were not able to do this, he was required to fast two months together, by way of penance. The fine for a man's blood was set in the "Sonna" at 100 camels, and was distributed among the relations of the deceased. Theft was ordered to be punished by cutting off the hand. As to injuries done to men in their persons, the law of retaliation, which was ordained by the law of Moses, is also approved by the Koran; but it was seldom executed; the punishment being generally turned into a *malct* or fine, paid to the party injured. In the punishment of lesser crimes, not provided for by the Koran, the Mahometans have commonly recourse to stripes or drubbing, according to the usual practice of the East. Under the head of the civil laws of the Mahometans, we may comprehend the injunction of warring against infidels, which is repeated in several passages of the Koran, and declared to be very meritorious in the sight of God; those who are slain fighting in defence of the faith, being reckoned martyrs, and promised immediate admission into paradise.

The months which the ancient Arabs held sacred were al Moharram, Rajeb, Dhu'ikaada, and Dhu'lkajja, the 1st, the 7th, the 11th, and the 12th in the year. Mahomet by the Koran confirmed the observance of these months.

The day of the week which Mahomet has set apart for public worship is Friday; besides which they have two annual feasts called *Beiram*.

After the death of Mahomet, a schism arose among his followers, which divided them into two great factions, whose separation not only gave rise to a variety of opinions and rites, but also excited the most implacable hatred, and the most deadly animosities. Of these factions, the one acknowledged Abubeker, the father-in-law of Mahomet, as his successor, or the true caliph, and its members were distinguished by the name of *Sunnites*; while the other adhered to Ali, his son-in-law, and were known by the title of *Schiites*. Both, however, adhered to the Koran as a divine law, and the rule of faith and manners; to which indeed the former added, by way of interpretation, the *Sonna*, *i. e.* a certain law, which they looked upon as descended from Mahomet by oral tradition, and which the Schiites refused to admit. Among the Sunnites we are to reckon the Turks, Tartars, Arabians, Africans, and the greatest part of the Indian Mahometans; whereas the Persians, and the subjects of the grand mogul, are generally considered as the followers of Ali, though the latter indeed seem rather to observe a strict neutrality in this contest. Besides these two grand factions, there are other subordinate sects among the Mahometans, which dispute with warmth concerning several points of religion, though without violating the rules of mutual toleration. Of these sects there are four, which far surpass the rest in point of reputation and importance, *viz.* the Hanefites, the sect of Malcc, the sect of Al Shafei, and that of Ebn Hanbal, which

are

are called the orthodox Mahometans. Sale's Preliminary Discourse. See ALCORAN.

The rapid success which attended the propagation of this new religion, was owing to causes that are plain and evident, and must remove, or rather prevent, our surprise, when they are attentively considered. We have enumerated the principal under the biographical article MAHOMET. But the subject is of importance, and we shall therefore here resume it. The terror of Mahomet's arms, and the repeated victories which were gained by him and his successors, were, no doubt, the irresistible arguments that persuaded such multitudes to embrace his religion, and submit to his dominion. Besides, his law was artfully and marvelously adapted to the corrupt nature of man; and, in a more particular manner, to the manners and opinions of the eastern nations, and the vices to which they were naturally addicted: for the articles of faith which it proposed were few in number, and extremely simple; and the duties it required were neither many nor difficult, nor such as were incompatible with the empire of appetites and passions. It is to be observed farther, that the gross ignorance under which the Arabians, Syrians, Persians, and the greatest part of the eastern nations, laboured at this time, rendered many an easy prey to the artifice and eloquence of this bold adventurer. To these causes of the progress of Mahometanism, we may add the bitter dissensions and cruel animosities that reigned among the Christian sects, particularly the Greeks, Nestorians, Eutychians, and Monophysites; dissensions that filled a great part of the East with carnage, assassinations, and such detestable enormities, as rendered the very name of Christianity odious to many. We might add here that the Monophysites and Nestorians, full of resentment against the Greeks, from whom they had suffered the bitterest and most injurious treatment, assisted the Arabians in the conquest of several provinces, in which, of consequence, the religion of Mahomet was afterwards introduced. Other causes of the sudden progress of that religion will naturally occur to such as consider attentively its spirit and genius and the state of the world at this time. Mosheim's Eccl. Hist.

MAHON, in *Geography*. See PORT *Maben*.

MAHON, a river of Ireland, in the county of Waterford, which runs into the sea; 11 miles E. of Dungarvan.

MAHONE BAY, a bay on the coast of Nova Scotia, separated from Margaret's bay by the promontory, on which is the high land of Aspotogoon.

MAHONING, a township of America, in Pennsylvania, situated on Susquehanna river.

MAHONNOY, a township of Susquehanna river, in Pennsylvania, having 1102 inhabitants.

MAHONY, a town of Hindoostan, in the circle of Sohagepour; 20 miles N. of Sohagepour.

MAHOU, a city of China, of the first rank, in the province of Setchuen, seated on the Kincha; comprehending, within its district, only one city of the third class, but a place of great trade. N. lat. 28° 32'. E. long. 103° 51'.

MAHOWLY, a town of Hindoostan, in Oude; 29 miles N.W. of Kairabad.

MAHR, HANNA, a town of Syria, where the Greek Catholics have a convent and a printing-office; 18 miles N.E. of Bairout.

MAHRABUT. See MARAHBUT.

MAHRAJEGUNGE, a town of Hindoostan, in Bahar; 11 miles E. of Hajypour.—Also, a town of Bengal; 30 miles N.E. of Purneah.—Also, a town of Hindoostan, 20 miles W. of Benares.

MAHRAS, EL, a town of Tunis; 60 miles S. of Cairoan.

MAHRATTAS, a powerful people of Hindoostan, who derived their name, as some say, from "Marhat," a province of the Deccan, mentioned by Ferishta, and comprehending Baglana, or Bogilana, and other districts, which at present form the most central part of the Mahratta dominions. The original meaning of the term Marhat is unknown; but there is no doubt that the name of the nation is a derivative from it; for we may depend upon the testimony of Ferishta, who wrote at a period, when the inhabitants of the province of Marhat did not exist as an independent nation; but were blended with the other subjected Hindoos of the Deccan. We learn also from an earlier authority than that of Ferishta, viz. from Nizam-ul-Deen, an officer in the court of Aebur, who wrote a general history of Hindoostan, brought down to the 40th year of that emperor, that one of the kings of Delhi made an excursion from Deogur, or Dowlatabad, into the neighbouring province of "Marhat." This relation occurs also in Ferishta's history of Hindoostan. It was in the reign of Alla I. A. D. 1312. From a paper published in the "Asiatic Researches," (vol. ix.) we learn that it is asserted in India, that the "Mahrattas" are foreigners, and that they acknowledge this to be their origin. A tribe called Ranas, related to the Mahrattas, say, that they are descended from Nushirvan; and the Parfis, in India, fix the time of their emigration in the reign of Abu-Becr, which lasted only two years, in 632 and 633. Some of these emigrants left Persia at different periods, in consequence of the fanatic zeal of the Mussulmen, and their persecuting spirit; but the emigration of the children of Nushirvan is the most ancient. Of these emigrants, some retained their ancient religion, and are called Parfis; others termed Hindûs, and are called Ranas and Mahrattas. The Mahrattas are called "Maha-Rashtas" in Sanscrit: "Maha" is great and illustrious, and "Rasht-ra," synonymous with Raja-putra, implies their royal descent; and their name also indicates, that they were acknowledged to belong to the second class on their arrival in India, and of course that they were not Brahmans. When the new adventurers obtained power and influence, they assumed the title of Maha-Rashtas, and by striking out such letters as became useless, when brought to the standards of the dialects in use, they acquired the name of Maha rata, Mahrata, and Mahrator. The founder of the Mahratta empire may be considered as Sevajee, who was born in 1628, and disdaining the condition of a subject, embraced an early opportunity of becoming independent. The progress of his conquests was so rapid, that he became formidable to the armies of the Mogul empire, before Aurungzebe's accession to power; having seized on the principal part of the province of Baglana, and the country of Concan, situated between it and the western sea. He had also taken possession of other places of strength. In the Carnatic he had possession of Gingee, together with an extensive district round it; and this, perhaps, may be regarded rather as an usurpation of one of the Visapour conquests, than as an acquisition made from the original sovereign of the Carnatic; for the king of Visapour appears to have possessed the southern part of the Carnatic, including Tanjore. At the death of Sevajee, in 1680, his domains extended from the northern part of Baglana, near Surat, to the neighbourhood of the Portuguese districts of Goa, along the sea-coast. His conquests had been the fruits of hardy and persevering valour; partly acquired in despite of Aurungzebe, then in the zenith of his power. Sevajee had also plundered Surat and Goleonda, and even attacked

attacked Goa, when the Portuguese power was at its height. His son Sambajee fell a sacrifice to his debauchery, having been seized on treacherously, in one of his licentious excursions, and cruelly put to death by Aurungzebe in 1689. The Mahrattas, however, remained unsubdued, and increasing in power. Sahoo, or Sahoojee, succeeded his father Sambajee, at a very early age; and as he inherited the ability and vigour of mind of his immediate ancestors, and reigned more than fifty years, during a period favourable to the aggrandizement of a rising state, the Mahratta power grew up to the wonderful height at which we have beheld it. The confusions occasioned by the disputed succession among Aurungzebe's sons, and their descendants, opened a wide field to all adventurers; and particularly to those hardy and enterprising people, who had contended even with Aurungzebe himself; and it would be matter of surprise that Sahoojee made so many conquests, if we did not consider that Hindoostan abounds with military adventurers, who readily enlist themselves under a chief, who holds out to his followers a prospect of plunder. At the time of Sahoojee's death, in 1740, the Mahratta state had swallowed up the whole tract from the Western sea to Orissa, and from Agra to the Carnatic; and almost the remaining portion of Hindoostan, Bengal excepted, had been over-run and plundered. It is difficult to trace the Mahratta conquests, according to the order of time in which they were made.

It is known that they took part in the disputes between the descendants of Aurungzebe at Delhi, as early as the year 1718; but it was not till the year 1735, that they were sufficiently powerful to demand a tribute from the emperor, Mahomed Shah. This terminated in their acquisition of the greatest part of the province of Malwa; and in a grant of the fourth part of the nett revenues of the other provinces in general. This proportion being denominated in the language of Hindoostan a "Chout," the subsequent demands of the Mahrattas were thus called, though they are not limited to that proportion. About the year 1736, they took part in the disputes between the nabobs of Arcot, in the Carnatic; and as the principal European settlements, on the coast of Coromandel, are situated within this district, these disputes eventually engaged the French and English East India Companies in scenes of hostility for several years. Sahoojee was succeeded, in 1740, by Ram Rajah, who was a weak prince; and it happened in the Mahratta state, as in other states of recent formation, and rapid growth, that what was gained by the ability of one despot was lost by the imbecility of another. The two principal officers of the state, the "Paishwah," or minister, and the "Bukshi," or commander in chief, agreed to divide the dominions of their master; the former assuming the government of the western provinces and continuing at Poonah, the ancient capital, and the latter occupying the eastern provinces and residing at Nagpour, in Berar. This violent usurpation of the empire by its ministers, encouraged the usurpations of others, according to their respective degree of power, and their opportunity; so that, in the course of a few years, the state, from being an absolute monarchy, became a mere confederacy of chiefs, exhibiting the most disjointed example of feudal government in the world. In 1742, and 1743, both the Mahratta states, for reasons which we shall not here recite, invaded Bengal, with armies said to contain 80,000 horsemen each. But as they acted without union, and Aliverdy had recourse to bribery, and to other means for creating a dissention between them, the inhabitants of Bengal, though great suf-

ferers, were not injured to the degree which they were led to expect. The Mahrattas did not retire from the provinces till the year 1744, when they had collected a vast mass of plunder and established the claim of the "Chout," which, however, was never regularly paid. The Berar Mahrattas having afterwards obtained possession of the Orissa province, their proximity to Bengal afforded them frequent opportunities of plundering the frontier provinces; and it was not till the year 1761, when Cossim Ally, nabob of Bengal, ceded the provinces of Burdwan and Midnapour to the English, that the Mahrattas ceased to plunder them. Bajiraw, who had taken possession of the Western provinces, wrested from the Portuguese the fortrefs of Basseeen, and the island of Salfette, near Bombay, which were inferior in importance only to Goa. He died in 1759, and left the paishwahship, now considered as an hereditary establishment, to his son Ballajée. At this period the Mahrattas pushed their conquests into the Panjab, and even to the banks of the Indus. But their prosperity was of no long duration. The wars that ensued between them and Abdalla of Candahar, and which terminated with the famous battle of Panniput, the most obstinate and bloody in the records of Hindoostan, decided the pretensions of the Mahrattas with regard to universal empire in Hindoostan, to which they were aspiring, for in this battle they lost the flower of their army, and their best generals; and from that period, viz. 1761, their power has been sensibly on the decline. Ballajée died soon after, and was succeeded by his son Maderow, who died in 1772. The son and successor of Maderow was murdered, in 1773, by his uncle Ragobak; by which act he excited general resentment and detestation; so that, needing allies to support his ill-gotten power, he made an advantageous treaty with the English, in order to secure the Bombay government in his cause; the consequence of this treaty was the commencement of hostilities both by sea and land, and the island of Salfette, a most desirable acquisition, was taken possession of by the English. A subsequent war between the English and the Mahrattas was attended with the conquest, on the part of the former, of the finest parts of Guzerat and the Concan, including the fortresses of Basseeen and Amedabad; and, in short, of the whole country from Amenabad to the river Penn, and inland, to the foot of the Gauts; and on the side of Oude, the province of Gohud and other districts, together with the celebrated fortrefs of Gwalior, were reduced; and the war was carried into the heart of Malwa. This war was attended with an enormous expence, and a contest broke out with Hyder Ally in 1780, and therefore, in 1782 and 1783 a peace was negotiated and concluded between the English and the Mahrattas; and all the acquisitions made during the war were given up except Salfette, and the small islands situated within the gulf formed by Bombay, Salfette, and the continent. The eastern Mahratta state, or that of Berar, though preserved from foreign wars, has had its share of intestine broils. It is not likely, says major Rennell, that either of the Mahratta states will soon become formidable to the other powers of Hindoostan. The eastern state has not resources for it, and as for the western, it is so divided between different chiefs, that it will not be easy for one of them to gain such an ascendancy as to reunite its divided power. These Mahratta states, the western and eastern, collectively, occupy all the southern part of Hindoostan proper; together with a large proportion of the Deccan, Malwa, Orissa, Candeeish, and Vissapour; the principal parts of Berar, Guzerat, and Agimere; and a small part of Dowlatabad, Agra, and Allahabad, are comprised

within their extensive empire, which extends from sea to sea, across the widest part of the peninsula; and from the confines of Agra northward, to the Kistnah southward; forming a tract of about one thousand British miles long, by seven hundred wide. To the western state, which is divided among a number of chiefs or princes, whose obedience to the paiswah, or head, resembles that of the German princes to the emperor, being merely nominal, and whose confederacy never takes place except for mutual defence, belong several "jaghiredars," or holders of "jaghires," one on the north of Poonah, and two on the south. The revenue of this state is not easily ascertained; but it has been stated by a native of India at 12 crores of rupees, or 12 millions sterling; and the net receipts, jaghires deducted, at five crores. The same account makes the military establishment in the field to be 200,000 troops, foot and horse; besides an equal number in garrison. Another account of the revenue reckons seven crores for the net revenue. Major Rennell observes that if the provinces possessed by this state were to be rated in the same proportion as in the time of Aurungzebe, the net revenue would be about eight crores of rupees, or eight millions sterling. The most powerful jaghiredar within this state is that of Sindia, who, since the Mahratta peace in 1783, has extended his frontier from Malwa towards the Jumnah, occupying most of the petty states that heretofore existed there, and particularly that of Gohud. He also extended his arms southward to Delhi, and into the provinces of Mewat and Jyenagur; reducing many fortresses and a considerable tract of country, which had been before possessed by the Jats and Nudjaff Cawn. The revenue of his paternal, or original dominions, in Malwa, &c. has been estimated at one crore of rupees *per annum*. Among his new acquisitions, Gohud is estimated at 20 or 30 lacks *per annum*; Holkar has been supposed to possess 80 lacks *per annum* in his share of Malwa. Sindia's capital city is Ougein, and Holkar's capital is Indore, about 20 cosses S. or S.E. of Ougein. For an account of Berar, see BERAR; and for further particulars relating to the Mahratta states, see HINDOOSTAN. Rennell's Introduction to his Memoir, passim, and his Map.

MAHRAUZEDURGAM, a town of Hindoostan, in Myfore; six miles N.N.E. of Kistnageri.

MAHRENBURG, or MARENBERG, a town of the duchy of Stiria; nine miles N. of Windisch Gratz.

MAHSENA, in *Ichthyology*. See SCIÆNA.

MAHU, in *Geography*, a town of Sweden, in Sudermanland; 28 miles N.W. of Nykioping.

MAHUDGEE, a town of Hindoostan, in Oude; 12 miles N. of Fyzabad.

MAHUDWAH, a town of Hindoostan, in Guzerat; 31 miles S.E. of Puttan Sumnaut.

MAHUR, a circar of Hindoostan, in Berar, on the N. side of the Godavery river, E. of Ellichpour, and N. of Tellingana. The chief towns are Mahur and Neermul.—Also, a town, the capital of the above circar, 112 miles E. of Ellichpour. N. lat. 19° 24'. E. long. 78° 3'.—Also, a town of Hindoostan, in the circar of Gurrak; 90 miles S.S.W. of Allahabad. N. lat. 124° 18'. E. long. 81 2'.

MAHUREA, of Aublet and Jussieu, in *Botany*. See BONNETIA.

MAHURRY, in *Geography*, a town of Hindoostan, in the circar of Surgooja; 35 miles N.W. of Surgooja.

MAI, a town of Persia, in the province of Laristan; 40 miles W. of Lar.

MAIA, a river of Russia, which, rising in N. lat. 59° 50'.

E. long. 139° 10', pursues a S.W. course to N. lat. 57° 40', and then uniting with the Maimakan, changes its course to N.N.W. and runs into the Aldan, N. lat. 60° 20'. E. long. 133° 40'.

MAJA, in *Ornithology*, the name of a bird described by Nieremberg as very common in the island of Cuba, and frequenting the fields of rice in large flocks. It is described to be a small bird of a yellowish colour, very delicate, and well tasted, and remarkable for having a stomach on the back or outside of the neck. See FRINGILLA *Maja*.

MAJA, or *Majan* of Buffon, a species of *Loxia*; which see.

MAIAGUE, the name of a Brazilian bird of the web-footed kind, but having its hinder toe loose. It is of the size of the common goose; its head is large and round; its neck long, and it always carries it crooked like a swan; its beak is strong and hooked at the end; it is all over of a brownish-black colour, except that its throat is yellow. It is found about the mouths of rivers, and feeds on fish; it builds on the ground; it is very nimble in running, flying, and diving, and is not easily taken, but is a very well-tasted fowl. It is the Brazilian *patrel* of Latham. See PROCELLARIA *Brasiliana*.

MAIAK, in *Geography*, an ostrog of Russia, on the coast of the Frozen ocean. N. lat. 71° 16'. E. long. 169° 14'.

MAIAKAR, a town of Russia, in the government of Perm; 16 miles N. of Obrinsk.

MAIAN, a town of Persia, in Faristan; 18 miles S. of Ispahan.

MAJANAH, a town of Algiers, in the province of Constantina, at the entrance of an extensive plain, to which it gives name; 50 miles S.S.W. of Boojeiah.

MAIANTHEMUM, in *Botany*, from *Μαΐ*, the month of May, and *ανθεμ*, a flower, a name given by some authors to the Lily of the Valley. See CONVALLARIA.

MAIAR, in *Geography*, a town of Persia, in Chufistan; 12 miles N. of Kosliua.

MAJARES, a town of Transylvania, in the Maros; 17 miles E. of Bitricz.

MAIDA, a town of Naples, in Calabria Ultra; 9 miles W.N.W. of Squillace.

MAIDEN, an edged instrument used in some countries, and formerly in Scotland, for the beheading of criminals.

The maiden is a broad piece of iron, of a foot square, sharp on the lower part, and loaded above with lead, so as scarcely to be lifted: at the time of execution, it is pulled up to the top of a narrow wooden frame ten feet high, with a groove on each side for the maiden to slide in. The prisoner's neck being fastened to a bar underneath, on a sign given, the maiden is let loose, and the head in an instant separated from the body. It has been lately much used in France as an instrument of decollation, under the name of *Guillotine*.

MAIDEN is also the name of a machine first used in Yorkshire, and since introduced into other places, for washing of linen; consisting of a tub nineteen inches high, and twenty-seven in diameter at the top, in which the linen is put, with hot water and soap, to which is adapted a cover, fitting it very closely, and fastened to the tub by two wedges; through a hole in the middle of the cover passes an upright piece of wood, kept at a proper height by a peg above, and furnished with two handles, by which it is turned backward and forward: to the lower end of this upright piece is fastened a round piece of wood, in which are fixed several pieces, like cogs of a wheel. The operation of this machine is to make the linen pass and repass quick through the water. Gent. Mag. vol. xxii. p. 32.

MAIDEN-Affixes, are those where no person is condemned to die.

MAIDEN-Hair, *Adiantum*, in *Botany* and *Medicine*. See *ADIANTUM*, and *ASPLENIUM*.

MAIDEN-Hair, Black, a name sometimes given to the dwarf-fern. See *ASPLENIUM*.

MAIDEN-Hair, English. See *TRICHOMANES*, and *ASPLENIUM*.

MAIDEN-Hair, White, or *Wall-Rue*. See *ASPLENIUM*.

MAIDEN Islands, in *Geography*, a cluster of small islands in Five Island harbour, near the W. coast of the island of Antigua.

MAIDEN Paps, a mountain of Scotland, in the county of Roxburgh; 8 miles from Havick.

MAIDEN Plum, in *Botany*. See *PLUM*.

MAIDEN-Rents, in our *Old Writers*, a noble paid by the tenants of some manors on their marriage. This was said to be given to the lord, for his omitting the custom of marcheta, whereby he was to have the first night's lodging with his tenant's wife; but it seems more probable to have been a fine for a licence to marry a daughter.

MAIDEN Rocks, in *Geography*, a chain of rocks in the East Indian sea, near the N. coast of the island of Java. S. lat. 7° 38'. E. long. 114° 36'.

MAIDENHEAD, anciently called *South Ealington*, a market-town in the hundred of Cookham, Berkshire, England, is situated 26 miles from London, on the borders of the Thames, in the parishes of Bray and Cookham. It consists principally of one long paved street; and derives its chief importance from the bridge, by means of which the great western road was carried through the town. Previously the road passed through Burnham, and travellers usually crossed the river at a ferry called Babham's End, about two miles north of Maidenhead. The original bridge, which was of wood, Camden says, was erected about the year 1400; but there is sufficient evidence of its being of greater antiquity, and that, in 1297, it had been built long enough to need repair; for which purpose, a toll for three years was then granted. The present bridge, which is a work of considerable merit, was constructed from the designs of sir Robert Taylor; and its foundation was laid in 1772. It consists of seven large semi-circular arches of stone, and three smaller, at each end, of brick. The expence of building it was 19,000*l.*, independent of some contiguous lands, which were purchased to render the work complete. The approach to this structure is grand and spacious, the ends being formed with curves outwards; along the sides is a broad pavement, fenced with a balustrade. Maidenhead was originally incorporated in the 26th year of Edward III., under the name of the guild or fraternity of the brethren and sisters of Maydeneth, or Maidenhithe. After the Reformation, a fresh incorporation was granted, in the name of the warden and burgessees of Maidenhead. King James II. granted another charter with the style of mayor, bridge-masters, and burgessees, who are empowered to choose a high-steward. Two of the burgessees, who are eleven in number, are annually elected bridge-masters. The high-steward, the recorder, the mayor, and his immediate predecessor, are justices of the peace. The mayor is clerk of the market, coroner, and judge of a court, which is held once in three weeks. The market, which was granted in 1452, is still kept on Wednesdays, and is a considerable mart for corn. Here are three annual fairs. The revenues of the corporation consist chiefly of the tolls of the market and bridge. The principal trade of the town is in malt, meal, and timber; and the inhabitants derive additional assistance from the continual passage of travellers, for whose accommodation several

inns have been opened. In that part of the town which lies within the parish of Cookham is a chapel, exempt from episcopal jurisdiction; the minister is appointed by the mayor and bridge-masters. In this division of the town is also an alms-house for eight poor men and their wives, founded and endowed in 1659, by James Smith, esq. citizen of London. The number of inhabitants in Maidenhead, as returned to parliament in 1801, was 949, occupying 160 houses: but either some mistake was made in that enumeration, or the population has been rapidly on the increase, for, in the year 1806, it amounted to 1100. At the eastern extremity of the town is a large brick mansion, the seat of sir Isaac Pocock, bart. Lyfons's *Magna Britannia*, vol. i. 4to. 1806.

MAIDENHEAD, a small neat village of America, in Hunterton county, New Jersey, situated on the road between Princeton and Trenton; 6 miles from each, and having a Presbyterian church: the township contained, in 1790, 1032 inhabitants.

MAIDEN-LAND, a name given by sir Richard Hawkins, in 1594, to land which he discovered in steering towards the straits of Magellan, in honour of queen Elizabeth, and which, as he says, lies "some three-score leagues from the nearest part of South America." This land was afterwards found to be two large islands by captain John Strong, of the *Farewell*, from London, who, in 1689, passed through the strait which divides the eastern from the western of those islands. To this strait he gave the name of Falkland's Sound, in honour of his patron, lord Falkland; and the name has been since extended, through inadvertency, to the two islands that are separated by it. See *FALKLAND'S Islands*.

MAIDHAT, a town of Persia, in the province of Irak; 55 miles S.S.W. of Dainur.

MAIDSTONE, a borough and market-town in the hundred of that name, lathe of Aylesford, and county of Kent, England. It is beautifully situated on the banks of the river Medway, whence it is supposed to have derived its name. The origin of this place is wholly uncertain. Camden, and some others, have considered it as the *Vagniacæ* of Antoninus, though upon very insufficient evidence. A few writers have also conjectured it to be the *Caer Meguiad*, or *Megwad*, mentioned in Nennius's Catalogue of British Cities; but this opinion is equally doubtful with the former. The Saxons named it *Medwegeston*, and it occurs in *Domesday-book*, by the appellation *Meddestone*, of which terms its present name is an easy and obvious corruption.

This town is a borough by prescription, and the capital of the county of Kent. In ancient times it was governed by a portreeve and twelve brethren. Edward VI., in the third year of his reign, formed it into a chartered corporation, by the style of the "mayor, jurats, and commonalty;" and about the same time members were first returned from hence to serve in parliament. The charter granted by this monarch was either renewed, or confirmed with additional privileges, by several successive kings. By the last charter, dated in 1748, the government was vested in a mayor, twelve jurats, forty common council-men, a recorder, two serjeants at mace, and other inferior officers. Freemen, not receiving alms, have the right of electing the burgessees to parliament.

Maidstone extends about a mile in length, from north to south, and somewhat more than three quarters in breadth, from east to west. The principal portion of its buildings stands on the eastern bank of the river, by which it is watered, rising gradually from its brink. It comprises chiefly four principal streets, which intersect each other; with some lesser ones branching off from them at right

angles. The high street, in particular, is very spacious, and mostly well-built. Every part of the town has been considerably improved within these few years. In 1791, an act of parliament was obtained for the purpose of having it new paved and lighted, and its different market-places repaired; which act has been carried into execution with great efficacy and judgment. The church, one of the largest parochial edifices in the kingdom, is a very handsome embattled building, consisting of a nave, aisles, and chancel. It is adorned with a lofty embattled tower, which formerly supported a spire, but the latter was destroyed by lightning in November, 1730. The windows are large, and ornamented with rich tracery, particularly that facing the east. By whom this church was first constructed, is uncertain; but it is well ascertained to have been rebuilt by archbishop Courtney in the time of Richard II. from whom he obtained a licence to render it collegiate, for the use of the warden, chaplains, and other members of the new college, then building close to the southern side of the cemetery. This prelate was buried in the centre of the chancel, in a grave about five or six feet deep, whence his bones were discovered in 1794; but his monument has been long since destroyed. On the north side of the chancel stands a very ancient defaced tomb, raised in honour of one of the Woodvilles, ancestors to king Edward IV. th's queen; and in the vaults within the communion-rails several of the ennobled families of Aitley and Marsham lie buried. At the corner of East-lane is the priory, or friary, so called from having been anciently the house of a convent of Franciscans, or Grey Friars, founded here by Edward III., but which was afterwards removed to Walsingham, in Norfolk. Faith's chapel, in the northern district of the town, appears to have been long used as a place of worship, but its history is very little known. The free grammar-school is a foundation of considerable repute, some of the first literary characters in this country having been educated here. The school-room, and part of the adjoining buildings, originally formed the chapel and lodgings of the "Fraternity of Corpus Christi," which was founded by a few of the inhabitants professing the rule of St. Benedict. Besides the free-school, there are two charity schools, established through the interest of the Rev. Dr. Josiah Woodward; two ranges of alm-houses, and a poor's-house, erected in 1720. The shire-hall, a good modern edifice, is appropriated to public business. The assizes for the county are held here, as are also the quarterly sessions, and other county courts. Adjoining to this place is a prison, called the *Brambles*, which anciently belonged to the archbishops of Canterbury, but now to the corporation. The gaol, in East-lane, erected in 1741, has since been much enlarged and improved. At the upper end of High-street is a conduit, which forms the chief reservoir for supplying the inhabitants with water. Another building, of the same kind, also stood in the middle of this street previous to the year 1793, when it was pulled down. A new octagon structure, in the lower part of the town, contains a third reservoir. The water which supplies these reservoirs is brought by pipes laid under the Medway, from an inclosed spring, called Rocky-hill, in the West-borough. The theatre, situated on the west side of High-street, is a neat small building. In Earl's-street is Earl's-place, a curious ancient stone mansion, having a large Oriel window, filled with painted glass, and at a short distance beyond Week-street are very extensive barracks, both for infantry and cavalry, the erection of which has greatly increased the population of the town.

Maidstone has been long celebrated as the first hop-market in the kingdom. Some manufactures, however, are likewise

carried on here. The linen trade, first established by a few refugees from the Netherlands, in the reign of queen Elizabeth, still continues to flourish. There are besides many paper-mills in the immediate neighbourhood, an extensive distillery of English spirits, or Maidstone Geneva, and some very considerable beer and porter breweries. The circumstance of the tide rendering the Medway navigable for vessels of fifty or sixty tons, contributes much to facilitate and encourage the trade of this town in all its departments.

The principal events of historical importance immediately connected with Maidstone, are the rebellion of sir Thomas Wyatt, and the battle fought here in 1648, between the Kentish loyalists and the parliamentary forces under general Fairfax, in which the former were defeated after a most sanguinary contest. The plague has at different periods made great ravages here. A sudden thaw, in January 1795, also occasioned considerable damage, not only in the town but in the adjacent country. Here was a palace belonging to the archbishop of Canterbury, now demolished.

The population of this town, according to the parliamentary returns of 1801, was estimated at 8027, viz. 3835 males, and 4192 females, of whom 5196 were returned as employed in various branches of trade, and 1306 in agriculture. The market days are Thursday in every week, and the second Tuesday of every month, when supplies of all kinds are abundant. The neighbourhood is adorned by a number of gentlemen's seats, spread throughout a fertile vale, where meadows, woodlands, rich orchards, and flourishing hop-grounds combine to exhibit a most extensive variety of picturesque and romantic scenery. Gibraltar-house, on the opposite side of the river from the town, forms an agreeable place of resort during the summer season. The Mote, the seat of the earl of Romney, lying about a mile to the S.E. of the town, was anciently the residence of the Wyatt family, and forfeited upon the attainder of sir Thomas by queen Mary. In the park, which is extensive, is erected a pavilion, on the spot where his majesty was entertained after the review of the Kent volunteers in 1799. Allington-castle, on the western side of the river, is still an interesting ruin. It is said to have been originally erected in the time of the Saxons by the noble family of the Columbavii, but being razed by the Danes, was rebuilt by the great earl Warrene. It was some time also the property of the Wyatts, and afterwards of the Aitleys. The chapel, a small gloomy edifice, contains several monuments in honour of the latter family. Newton's History and Antiquities of Maidstone, 8vo. Haisted's History, &c. of Kent, 4 vols. folio, and 12 vols. 8vo. Also, Beauties of England and Wales, vol. vii.

MAIDSTONE, a township of America, in Essex county, Vermont, on Connecticut river, containing 152 inhabitants.—Also, a township of Upper Canada, between Sandwich and Rochester, upon lake Erie.

MAJESTY, MAJESTAS, a title or quality given to kings; and which frequently serves as an appellation to distinguish them by.

The word seems composed of the two Latin words, *majus*, greater, and *status*, state.

The emperor is called, his Cæsarian or Imperial majesty; the king of Spain, his Catholic majesty; the king of France, formerly, his most Christian majesty; the king of Great Britain, his Britannic majesty, &c. Some have also extended this title to the popes.

Pasquier observes, that our forefathers used this quality very sparingly; and that the frequent use of the word, which now obtains, had not its beginning before the reign of their Henry II. He instances several letters of St. Gre-

gory, who, writing to king Theodoret and Theodoric, only compliments them with excellency.

Till the time of Charles V. the king of Spain had no title, but that of highness; Louis XI. was the first in France who assumed this title; and before our king Henry VIII. the kings of England were only addressed under the titles of grace, which began in the time of Henry IV., and excellent grace, under Henry VI., and highness. See KING.

At the peace of Munster, there was a great contest between the ministers of the emperor and those of France; the first would not allow the title of serenity to the king of France, and the latter would not give that of majesty to the emperor. At last it was agreed, that whenever the French king should write with his own hand to the emperor, he should give him the title of imperial majesty; and reciprocally, when the emperor should write to the king, he should give him that of royal majesty.

Under the Roman republic, the title majesty, *majestas*, belonged to the whole body of the people, and to the principal magistrates; so that to diminish or wound the majesty of the commonwealth, was to be wanting in respect to the state, or to its ministers. But the power afterwards passing into the hands of a single person, the appellation of majesty was transferred to the emperor, and the imperial family. Pliny compliments Trajan on his being contented with the title of greatness; and speaks very invidiously of those who affected that of majesty. And yet majesty seems to be the most modest and just title that can be attributed to sovereigns, since it signifies no more than the royalty, or sovereign power.

MAIEUL, *St.*, Regular Clerks of. See FATHERS of *Somasquo*.

MAIG, in *Geography*, a river of Ireland, in the county of Limerick, which rises in the Galtees, crosses the county, and falls into the Shannon, some miles below Limerick.

MAIGNAN, EMANUEL, in *Biography*, an able philosopher and mathematician, was born at Toulouse in the year 1601. He gave early indications of an inquisitive disposition and an inclination for learning. He went through a course of grammar-learning at the college of the Jesuits; here he spent his vacant hours in improving his mind, and at eighteen years of age he determined to renounce the world, and was admitted into the fraternity of the Minims. In studying philosophy, he became dissatisfied with the principles of Aristotle, and took every opportunity of exposing them to contempt. He took delight in inventing and solving geometrical problems, which he could do with ease and accuracy, though at this time he had never seen the Elements of Euclid, nor any other book written with the same view. When his mathematical acquirements were discovered, he was immediately appointed by his superiors to the mathematical chair, which he filled with such address and judgment, that his reputation soon spread beyond the boundaries of his own country. He obtained higher preferment, and rendered himself distinguished by his mathematical discoveries and physical experiments, which extorted the applause and admiration of those who were most conversant in those sciences. A circumstance that contributed to extend the fame of his learning, was a contest which arose between him and father Kircher concerning an invention in optics. In 1648, Maignan printed at Rome his treatise "De Perspectiva Horaria," which met with a very favourable reception, and which contains a method of making telescopes, invented by himself, which he fully explains without any attempt at mystery or disguise. In the year 1650, Maignan returned from Rome to Toulouse, and was created pro-

vincial, and in 1652 he published, in Latin, his "Course of Philosophy," in four volumes, octavo, by which he might be considered as the restorer of it. When this work appeared, the adherents to the Aristotelian system insisted that it was impossible to reconcile the author's opinions with the truths of religion. This objection Maignan undertook to refute, in a work entitled "Philosophia Sacra." In 1657 he was chosen to supply the place of father Merfenne, in a society of learned men, who held their meetings at the house of Henry Lewis de Montmort, master of the requests. In 1660, when Lewis XIV. passed through Toulouse on his return from his marriage, he visited the cell of father Maignan as one of the most curious objects in the province. The monarch was so struck with what he saw, that he was desirous of transplanting the venerable father to his capital, but he had higher objects in view than to shine in courts; he was seeking after truth, and endeavouring to enlarge the boundaries of science, and preferred the obscurity of a cloister to the splendour attached to a palace. In 1662, father Maignan published the first volume of his "Philosophia Sacra," which drew him into a long controversy with several learned opponents, of which a full account is given by Bayle. In 1672 he published replies to all his antagonists, and in the same year he gave the world the second volume of his "Philosophia Sacra," which was followed by a dissertation "De usu licito Pecuniarum." These literary labours did not prevent him from reading lectures to his pupils, and superintending the instruction of the younger members of his order. Besides this he was engaged in an extensive correspondence with the principal philosophers of his own age. Scarcely was any man more industrious than Maignan: to use the expression of one of our countrymen, it might be said, that "Leisure and he had taken leave of one another" from an early period of his life. He is said to have studied in his sleep; for in his dreams he was often employed on some theorems, the deductions of which he pursued till he arrived at their demonstration; and he was often suddenly awakened by the excessive pleasure which he felt in such discoveries. He died at Toulouse in 1676, in the seventy-fifth year of his age. The innocence of his life, the simplicity of his manners, and his amiable virtues, rendered him no less the object of esteem, than he was of respect, on account of his genius and learning. Bayle. Moreri.

MAIHERGA, in *Geography*, a town of Africa, in Sahara; 100 miles S.S.E. of Algiers.

MAII INDUCTIO, in *Antiquity*, denotes an ancient custom for the priest and people of country villages to go in procession to some adjoining wood on a May-day morning; and return with a May-pole, boughs, flowers, garlands, and other tokens of the spring. This May-game, or rejoicing at the coming of the spring, was for a long time observed, and still is in some parts of England; but it was condemned and prohibited in the diocese of Lincoln by bishop Grotthead.

MAJIR, in *Geography*, a town of Africa, in Biledulgerid. N. lat. 33° 30'. E. long. 6° 29'.

MAIL, MAILLE, is primarily applied to the meshes or holes in net-work.

This term in heraldry originally expressed the mesh of a net, and is derived from *macula*, Lat. or *mafcle*, Fr. signifying the same. Richlet says, *mailler* is used as a verb neuter, to express the art of netting. Some derive it from the Irish word *mala*, said to signify armour; or the word *mail*, which in Welsh properly means steel, and metaphorically hardness and armour. (See Rowland's *Mona Antiqua*.) Boyer in his French Dictionary translates the word *maille*, a little iron ring.

MAIL, Black. See **BLACK Mail.**

MAIL, Coat of. See **COAT of Mail.**

It is called also an *Habergeon*; which see.

Anciently they also wore shirts of mail under the waist-coat, to serve as a defence against swords and poniards. We also read of gloves of mail.

Of mail there are two sorts, *viz.* chain and plate mail. Chain mail is formed by a number of iron rings, each ring having four others inserted into it; the whole exhibiting a kind of net-work, with circular meshes, every ring separately rivetted. This kind of mail answers to that worn on the ancient breast-plates; whence they were denominated "*loricæ hammatæ*," from the rings being hooked together. Thus, "*Loricam confertam hamis, auroque trilicem*," Virg. *Æn.* l. iii. v. 67. Plate mail consisted of a number of small laminæ of metal, commonly iron, laid one over the other, like the scales of fish, and sewed down to a strong linen or leathern jacket, by thread passing through a small hole in each plate. This was exactly the form of the ancient "*lorica squammofa*." Similar to this is the Sarmatian cuirasse (see **CUIRASSE**), described by Pausanias, as quoted by Lipsius and Montfaucon. They take the hoofs of their horses, which they cleanse and polish, and then cut in little pieces like dragon's scales; which done, they bore the scales, and afterwards sew them with the sinews of an ox or horse: the dragon's scales resemble the divisions in a pineapple when it is green. Thus they make their cuirasses, which, for beauty and strength, are not inferior to those of the Gauls, for they very well sustain both distant and close blows; whereas the cuirasses of linen are not so sure, nor proof against iron. The linen ones are commodious for hunters, as the lions and leopards cannot penetrate them with their teeth. The cuirasse covered the body before and behind: it consisted of two parts, a breast and back piece of iron, fastened together by means of straps and buckles, and other similar contrivances. They were originally, as the name imports, made of leather, but afterwards of metal, both brass and iron. To the cuirasse was buckled the armour for the shoulders and arms; the first called "*pouldrons*," the second "*brassarts*," *garde bras, les avant bras*, and corruptly in English "*vambraces*." At the joint or bending of the arm, the *vambraces* were cut obliquely; the vacancies on the inside, when the arms were straightened, were covered by pieces of mail called "*gouffets*," and afterwards by a contrivance of plates resembling hearts. Cuirasses with entire sleeves of mail are mentioned by different military writers. A defence for the arms, called "*splints*," constituted part of the suit denominated an "*almaine ryvett*." The hands were defended by gauntlets, sometimes of chain mail, but more frequently of small plates of iron, rivetted together; in imitation of the lobster's tail, so as to yield to every motion of the hand. Some gauntlets inclosed the whole hand, as in a box or case; others were divided into fingers, each finger consisting of eight or ten separate pieces, the inside being gloved with buff leather: some of these reached no higher than the wrist, others to the elbow; the latter were styled long-armed gauntlets, many of which are to be seen in the Tower of London. The thighs of the cavalry were defended by small strips of iron plate, laid horizontally over each other, and rivetted together, forming what were called "*cuissearts*," or thigh pieces: of these some entirely enclosed the thighs, and others only covered the front of them, the inside next the horse being unarmed. They were made flexible at the knees by joints, like those in the tail of a lobster, and were called "*genouillieres*," or knee-pieces. Tassets, or shirts, hooked on to the front of the cuirasse, were used by the infantry.

For the defence of the legs were worn a sort of iron-boots, called "*greeves*." Plates of iron covering the front of the leg were also frequently worn over the stockings of mail. The greeves commonly covered the whole leg, as in the armour of John of Gaunt, and that of Henry VIII.; with these they had broad-toed iron shoes, with joints at the ankle; sometimes they had sabatons of mail. Boots of jack-leather, called *curboully* (*cuir bouille*), were also worn by horsemen: these are mentioned by Chaucer. The "*hauberk*" was a complete covering of mail from head to foot. It consisted of a hood, joined to a jacket with sleeves, breeches, stockings, and shoes, of double chain mail, to which were added gauntlets of the same construction. Some of these hauberks opened before like a modern coat; others were closed like a shirt. In France only persons possessed of a certain estate, called "*un fief de hauber*," were permitted to wear a hauberk, which was the armour of a knight; esquires might only wear a simple coat of mail, without the hood and hose. The "*haubergeon*" was a coat composed either of plate or chain mail, without sleeves; the shirt of mail was much in the form of the shirts now worn, except that it had no sleeves: it was always of chain mail. Grose's *Mil. Antiq.* vol. ii. See **ARMOUR**.

MAIL, or *Mall*, also signifies a round ring of iron; whence the play of pall-mall, from *palla*, a ball, and *maille*, the round ring on which it is to pass.

MAIL is likewise used for the leathern bag in which letters are carried by the post.

MAIL-Coach, a carriage particularly and expressly appropriated for the conveyance of letters to all parts of Great Britain. It is distinguished for its expedition and security; two most important considerations in a populous, commercial, and wealthy country. Previous to the year 1784, letters were conveyed from the metropolis to distant parts of the kingdom, and *vice versa*, by carts with a single horse to each, or by boys on horseback; in consequence of which, many robberies were committed, delays occasioned, and losses sustained. John Palmer, esq. afterwards comptroller-general of the post-office, devised a new plan, which he recommended to government, as calculated to increase the revenue, accommodate the public, and be highly advantageous to all parties. His proposal was acceded to, and the inventor has been rewarded with a large annual income. His plan was to provide a certain number of coaches, of light construction, and each to be adapted to carry the various bags or packets of letters, which were destined for a particular part of the country, or line of road. All the coaches were to leave London precisely at 8 o'clock in the evening, and to arrive at and leave certain post-towns at specific times. Each coach is drawn by four horses, travels at the rate of eight miles an hour, including the time allowed for change of horses, &c; and each coach is provided with a coachman, a guard with fire-arms, and allowed to carry four passengers inside, and two outside. The present fare (1812) is about *6d. per mile* for each of the former passengers, and *4d.* for the latter. The systematic regularity, punctuality, superior safety, and expedition of the mail-coaches of England render them peculiarly eligible and convenient for travellers. The property and profits of the post, or conveyance of letters, are vested in government, which contracts with the proprietors of coaches for the carriage of the mail; but these proprietors derive their chief profit from the fare of passengers, and carriage of small packets. The mail-coach establishment is under the superintendance of T. Halker, esq. For further particulars, see *Post Office*. The mail-coaches run above 13,000 miles daily. There is a similar establishment in Ireland.

MAILAH, in *Geography*, a river of Africa, which rises in the Sahara, and discharges itself into the Shott.

MAILCOTTA, or **MILGOTTAH**, a town of Hindoostan, in the Myfore; where the Mahratta chiefs met lord Cornwallis in the year 1791; 15 miles N. of Seringapatam.

MAILED, implies a thing speckled, or full of specks; as the feathers of hawks, partridges, &c. or the furs of some wild beasts.

MAILLA, **JOSEPH-ANNE-MARY DE MOYRIAC DE**, in *Biography*, a Jesuit missionary, was born at Maillac, and, having been educated by the society, was sent on the mission to China in 1703. He was employed by the emperor Kam-hi, with other missionaries, to make the map of China and Chinese Tartary, which was engraved at Paris. He afterwards made particular maps of several of the provinces. Being fixed at the imperial court, he had access to the "Great Annals of China," which he translated into French, and sent over his MS. to France, where it was partly printed, and intended to make 12 volumes 4to. This work forms the most complete history of the Chinese empire. Mailla died at Pekin in 1748, in his 79th year, after a residence of 45 years in China. His remains were interred at the expence of the emperor Kien-Long.

MAILLE, in the *French Coinage*, denotes a small weight used for gold and silver, 40 of which are equal to the ounce, or one-eighth of the mark = 3778 English grains.

MAILLE, in our *Old Writers*, a small kind of money. Silver half-pence were likewise termed mailles, 9 Hen. V. By indenture in the mint, a pound weight of old sterling silver was to be coined into three hundred and sixty sterlings, or pennies, or seven hundred and twenty mailles, or half-pennies, or one thousand four hundred and forty farthings: Hence the word maille was derived, which is now vulgarly used in Scotland to signify an annual rent. Hence *white maille*, white rents, (vulgarly called quit-rents,) were rents made in silver; and *black maille* denoted properly rents paid in cattle, otherwise called *neat gelt*; but more largely it was used to signify all rents not paid in silver. See **BLACK Maile**.

MAILLET, **BENEDICT DE**, in *Biography*, born of a good family of Lorraine in 1659, was nominated, at the age of thirty-three, consul-general of the French nation in Egypt: after which, he obtained the consulate of Leghorn. In 1715 he was appointed to visit all the factories of Barbary and the Levant; and executed his commission so much to the satisfaction of the government, that he obtained leave to retire with a pension. He died at Marseilles in the year 1738. He had, during his whole life, been a diligent student of natural history, which his lively fancy turned into system, which for some time interested the public. He maintained that all the land of this earth, and its vegetable and animal inhabitants, rose from the bosom of the sea, on the successive contractions of the waters: that men had originally been tritons with tails; and that they, as well as other animals, had lost their marine, and acquired terrestrial forms, by their agitations when left on dry ground. The work was published after the death of its author, by La Maserie; who also published, in 1743, "A Description of Egypt," drawn up from the papers of De Maillet.

MAILLEZAIS, in *Geography*, a town of France, in the department of the Vendée, and chief place of a canton, in the district of Fontenay-le-Comte; 6 miles S. of Fontenay. This was once the see of a bishop, since removed to Rochelle. The place contains 1350, and the canton 12,622 inhabitants, on a territory of 200 kilometres, in 13 communes.

MAILLS, on *Ship-board*, are square machines, composed of a number of rings interwoven net-wise, and used for rubbing off the loose hemp which remains on lines or white cordage, after it is made.

MAIMATSCHIN, in *Geography*, a Chinese frontier town, or village, on the confines of Siberia, opposite to *Kiakta*, which see. Its name denotes the "fortress of commerce." It is situated about 140 yards S. of the fortress of *Kiakta*, and nearly parallel to it. Midway between this place and the Russian fortresses, two posts about 10 feet high are painted, in order to mark the frontiers of the two empires; one is inscribed with Russian, the other with Manshur characters. Maimatschin is fortified with a wooden wall, and a small ditch about three feet broad; the latter having been dug in the year 1756, during the war between the Chinese and Kalmucs. The town is of an oblong form; its length is 700 yards, and its breadth 400. On each of the four sides a large gate faces the principal streets; and over each of these gates is a wooden guard-house for the Chinese garrison, which consists of Mongols in tattered clothes, and armed with clubs. Without the gate, which looks to the Russian fortresses, at the distance of about eight yards from the entrance, the Chinese have raised a wooden fence, so as to interrupt all view of the streets from without. This town contains 200 houses, and about 1200 inhabitants. Its two principal streets, about eight yards broad, cross each other in the middle at right angles, with two by-streets running from north to south. They are not paved, but laid with gravel, and kept very clean. The houses are spacious, uniformly built of wood, and of only one story, about 14 feet, in height: they are plaistered and white-washed; they are constructed round a court-yard of about 70 feet square, which is strewed with gravel, and appears neat. Each house consists of a sitting-room, some warehouses, and a kitchen. The windows are large, and, on account of the dearth of glass and Russian talc, are generally of paper, excepting a few panes of glass in the sitting-room. The aspect of the sitting-room is seldom towards the streets: it is a kind of shop, in which the several patterns of merchandize are placed in recesses, fitted up with shelves, and secured with paper doors for the purpose of keeping out the dust. In this room there are several niches, covered with silken curtains, before which are placed lamps; that are lighted upon festivals: these niches contain painted paper idols, a stone or metal vessel, in which the ashes of incense are collected, several small ornaments, and artificial flowers. The south-west quarter of the town is inhabited by the merchants of Bucharia, who bring to Russia cotton, stuffs and half-silks, spun and raw cotton, lamb-skins, precious stones, gold dust, unprepared nitre, sal ammoniac, &c. The governor of Maimatschin has the care of the police, as well as the direction of all affairs relating to commerce: he is generally a person of rank, often a mandarin, who, having been guilty of misconduct in some other station, is sent here by way of punishment. His power is considerable; and though his salary is not large, the presents he receives annually from the merchants amount to a considerable sum. The most remarkable public buildings in Maimatschin are the governor's house, the theatre, and two pagodas. In the small pagoda is a picture representing the god Tien, which, according to the explanation of the most intelligent Chinese, signifies the most high God, who rules over the 32 heavens. He is represented in a sitting posture, with his head uncovered, and encircled with a ray of glory; holding in his right hand a drawn sword, and extending his left as in the act of giving benediction. On one side of this figure are two youths; on the other a maiden and a grey-headed old man

man are delineated. In this temple there are no altars: it is opened only on festivals, and strangers cannot see it without a special order. The great pagoda, which is larger and more magnificent than the former, is accessible to all strangers, under the conduct of a priest. We cannot here describe in detail the various parts of this structure: the temple, which is an elegant Chinese building, and richly decorated, contains five idols of a colossal stature, filling the whole northern side. The principal idol is denominated "Ghedsur," or "Gheffur Chan;" his size is gigantic, and his face glitters like burnished gold; on his head he has a crown, and his garments are made of the richest silk; in his hand is a tablet, to which he directs a steady attention. Two small female figures, resembling girls about 14 years of age, stand on each side of the idol. The other idols are of an enormous size, though less in magnitude than Gheffur Chan. Tapers and lamps are kept burning day and night before the idols. There are various utensils in the temple, marked with Chinese devices and inscriptions; and, among others, a hollow wooden black lacquered helmet, which all devout persons strike with a wooden hammer, whenever they enter the temple. The first day of the new and full moon is appointed for the celebration of worship, upon each of which days no Chinese ever fails to make his appearance once in the temple. Their principal festivals are held in the first month of the year, called the white month, and answering to our February. Mr. Pallas has given us the following description of their superstitious behaviour during an eclipse of the moon. At the close of the evening in which it appeared, all the inhabitants were employed in raising an uproar, by hideous shrieks, knocking wood, and beating cauldrons; which noise was heightened by striking the bell and beating the kettle drums of the great pagoda. The Chinese suppose, that during an eclipse the wicked spirit of the air is attacking the moon, and that he is frightened away by these hideous shrieks and noises. When a fire occurred at Maimat'chin, none of the inhabitants attempted to extinguish it, but stood round it in idle consternation, occasionally sprinkling water on the flames, in order to soothe the fire god, who, as they imagined, had chosen these houses for a sacrifice.

The merchants of Maimat'chin come from the northern provinces of China, chiefly from Peking, Nanking, Sandchue, and other principal towns. They come hither without their wives and families; for there is not one woman at Maimat'chin. This circumstance is owing to the policy of the Chinese government, which totally prohibits women from having the slightest intercourse with foreigners. For the mode of carrying on commerce between the Chinese and Russians, and the principal articles which they mutually exchange, we refer to the article *KIAKTA*.

MAIMBOURG, LEWIS, in *Biography*, an ecclesiastical historian, was born at Nancy, in France, in the year 1610. When sixteen years of age he was entered in the society of Jesuits, and soon became a teacher of the classics in their schools. He was much celebrated afterwards as a preacher, though he has been generally charged with introducing into the pulpit low and vulgar descriptions, and sallies of wit, or even buffoonery, highly unbecoming his sacred office. As a writer, as well as a preacher, he was perpetually attacking the Janfenists, and in 1682 he wrote a treatise against the pretensions of the church of Rome, and in support of the liberties of the Gallican church: on account of this he was ordered by pope Innocent XI. to be expelled the society. For this disgrace, the king made him ample recompence by the grant of a pension, on which he retired to the abbey of St. Victor at Paris, where he died in 1686, at the age of

seventy-six. He was a very voluminous writer; his historical productions originally formed sixteen volumes, in 4to.; they consist of "The History of the Crusades;" "The History of the League;" "The History of the Decline of the Empire after Charlemagne;" "The Histories of the Pontificates of St. Gregory the Great, and of Leo;" "The History of the Schism of the Greeks; and of the Schism in the East;" "The Histories of Arianism; of the heresy of the Iconoclasts; of Lutheranism; and of Calvinism." Bayle. Moreri.

MAIMONIDES, MOSES, or Moses the son of Maimon, a Jewish rabbi, was born at Cordova, in Spain, in 1131. He has, by way of eminence, been called "The Doctor," and "The Eagle of the Doctors." He was, in every sense of the term, descended from illustrious ancestors, six of his ancestors having been distinguished by the title of wise. The early part of his education was undertaken by his father; who in due time provided him tutors from the most learned men of his age. He possessed very superior abilities, and made a rapid progress in all the branches of knowledge to which his attention was directed. He was perfectly skilled in the Hebrew, Arabic, Chaldee, Turkish, Median, and other languages. With all the branches of philosophy and the mathematics he was intimately acquainted, and also with Jewish jurisprudence, as is evident, not only by the comments with which he illustrated the whole body of laws of the Hebrews, but by the ability and judgment with which, from a confused and most intricate mass, clothed in corrupt and varying dialects, he reduced them to a regular system, written in pure Hebrew, and in an easy and elegant style. He likewise acquired a profound knowledge of the medical art, in the practice of which he attained the highest reputation. His very extraordinary talents and accomplishments in almost every species of learning excited the jealousy of his contemporaries; to avoid the ill effects of this, he resolved to quit Spain, and remove into Egypt, before he was thirty years of age. From this circumstance, and from his residing in that country during the remainder of his life, he is, by some writers, called "Moses Ægyptius;" by others he is named "Moses Cordubensis," from the place of his birth. In Egypt he opened a school, to which a number of pupils resorted from all parts, and particularly from Alexandria and Damascus, who made such improvement under his instructions, that they proved the means of spreading his fame throughout the world. He was appointed physician to Saladin, sultan of Egypt, who entertained for him the highest respect. His reputation was so great that he was applied to for advice and counsel by persons of the very first rank. Among others, the rabbi Aben Tybbon, wishing for a solution of some serious difficulties, on important points, proposed to pay him a visit, that they might discuss the matters at length in conversation. To which Maimonides replied, that nothing would afford him greater pleasure than such an interview: nevertheless he could not encourage him to undertake so long a voyage, because his own time was so fully occupied, that he could scarcely promise him his company for a single hour, either in the day or at night: "I live," said the learned doctor, "in Egypt, at the distance of nearly two sabbath-days' journey from Al-Cairo, where the king resides. On him the duties of my appointment require a very regular attendance. I generally visit him every morning; but when either himself, or any of his children, or of his concubines, are sick, I am not allowed to stir from the palace, so that I very often spend the whole day at court: if I find nothing amiss at court, I return home towards noon, but when arrived at my house, almost famished for want of food, I find all the approaches to it crowded with

with Gentiles and Jews, men of all ranks who have been impatiently waiting my return. No sooner have I alighted from my horse, and washed my hands, than I humbly request the indulgence of the multitude till I have appeased my craving appetite. As soon as I have dined, I examine the cases of my patients, and prescribe for them. This employment commonly lasts till night, when I am so overcome with the fatigue of hearing, speaking, and prescribing, that I can scarcely speak any longer, or even keep myself awake." Maimonides, after having spent a long and most useful life, died at the age of seventy, in the 1204th year of the Christian era, and was interred, with the highest funeral honours, in the land of Canaan. For three whole years did the people at large bewail his death, and they called the year in which it took place, "Lamentum Lamentabile;" and in speaking of him, they used to say, that from the time of Moses the prophet, no one approached so nearly to him in wisdom and sound learning, as Moses the son of Maimon. He is frequently designated in the writings of the Jews by the name of Rambam, the consonants of which are the initials of the words Rabbi Moses Ben Maimon. Notwithstanding his avocations as a physician, he devoted much of his time to the composition of learned works, a few of which may be mentioned: the first, in the order of time, was his "Pirush Hemishnah," or, a commentary on the Mishna, which he began in Spain, when he was in the twenty-third year of his age, and finished in Egypt, when he was about thirty. It was written in the Arabic language, and translated into Hebrew by Rabbi Aben Tybbon. The best edition of this work is published with the Mishna, at Amsterdam, in 1698, in 16 volumes, folio. The prefaces were published in Arabic, but in the Hebrew characters by our countryman Dr. E. Pococke, under the title of "Porta Mosis," in the year 1655. The next work to be noticed is entitled "Jad Chazekeh," or *Strong Hand*, which is also named "Mishna Hathora," or *The Reception of the Law*; it consists of a compendium of the *Talmud*, which see, and presents a complete code of Jewish, civil, and canon law, with a commentary. The best edition is that of Amsterdam, in 1702, in four volumes, folio. The principal work of this great man is entitled "More Nevochim," or *Guide to the Perplexed*, which is partly critical, partly philosophical, and partly theological; its design being to illustrate and explain the meaning of the scriptures. It was translated from the Arabic into Hebrew by R. Aben Tybbon, in the year 1551, and published at Venice; Buxtorf the younger gave an excellent version of it in the Latin tongue, which was published at Basil in 1629. Another important work of Maimonides is his "Seph'er Hamitzoth," or *Book of Commandments*, containing an exposition of the precepts of the Mosaic law. The titles of the other pieces of Maimonides may be seen in *W. liii Biblioth. Heb.*

MAIN, EAST, or *Stude river*, in *Geography*, a river of Canada, which runs into James bay. N. lat. $52^{\circ} 18'$. W. long. $78^{\circ} 45'$. On the east of this river is *East Main Houfe*, a station for the Indian trade in Canada. N. lat. $52^{\circ} 15'$. W. long. $78^{\circ} 42'$.

MAIN, a town of Persia, in the province of Farfistan; 14 leagues N. of Schiras; the inhabitants of which being descendants of the ancient Spartans, have never yet been conquered by the Turks.

MAIN, *Chief*, or *Principal*. Thus the main-mast is denominated, in contradistinction to the fore or mizen-mast: the main-keel, main-wales, main-hatchway, main-breadth, &c. are thus distinguished from the false-keel, channel-wales, and the fore and after hatchways. The main breadth is the broadest part of the ship, and is contained

between the upper and lower heights of the breadth lines.

MAIN-body of an army, is the body of troops that marches between the advance and the rear guard. In a camp it is that part of an army which is encamped betwixt the right and left wings.

MAIN-guard. See *Great and Main Guard*.

MAIN Harmonique, Fr. See *HARMONIC-Hand*, *HEXACHORDS*, and *SOLMISATION*.

MAINA, in *Geography*, a sea-port town of the *Morea*, near the W. coast; 30 miles S. of *Mistra*.

MAINBAYA, a town of *Ava*; 15 miles N. of *Prome*.

MAINBURG, a town of Germany, in the circle of *Bavaria*, on the *Ambs*; 32 miles N.N.E. of *Munich*.

MAINE, a division of France, before the Revolution, which was divided into *Upper and Lower Maine*; about 18 miles long and 20 broad. It now chiefly forms the departments of the *Mayenne and Sarte*.—Also, a river of Germany, which rises in the marquisate of *Culmbach*, on the confines of *Bohemia*, and after passing by a number of principal towns, joins the *Rhine*, a little above *Mentz*.

MAINE, a district or province of the *United States of America*, belonging to the *Massachusetts*, bounded on the N. by *Lower Canada*, E. by the province of *New Brunswick*, S. by the *Atlantic ocean*, W. by *New Hampshire*, from which it is partly separated by the *Piscataqua river*, and situated between N. lat. 43° and $48^{\circ} 15'$, and between W. long. $64^{\circ} 53'$, and $70^{\circ} 39'$. Its average length and breadth are each 200 miles; and it contains 40,000 square miles, or 25,600,000 acres. The district of *Maine* is divided into seven counties, as in the following table.

Counties.	No. of Inhabitants.		Chief Towns.
	1700.	1800.	
York	28,821	37,729	York.
Cumberland	25,459	37,921	Portland, the metropolis of the district.
Kennebeck	—	24,394	Augusta.
Lincoln	29,962	30,100	Wiscasset.
Hancock	9,549	16,316	Castine.
Washington	2,758	4,436	Machias.
Oxford	—	—	—
Total	96,540	150,896	—

The chief rivers of this district are *Penobscot*, *Kennebeck*, *Saco*, *Androscoggin*, *St. Croix*, &c. The most noted lakes are *Moosehead*, *Seodri*, *Sebacooc*, and *Umbagog*. The principal bays are those of *Casco*, *Penobscot*, *Machias*, *Saco*, and *Passamaquoddy*. Its most remarkable capes are those of *Neddock*, *Porpoise*, *Elizabeth*, *Small Point*, *Pemaquid*, and *Petit Manan*. Almost the whole coast N.E. of *Portland* is lined with islands, among which vessels may generally anchor with safety. This district, though an elevated country, cannot properly be denominated mountainous. The soil is generally arable and very fertile, more especially between *Penobscot* and *Kennebeck* rivers. On some parts of the sea-coast the lands are but indifferent; but they might be much improved by manuring them with the rock-weed, which grows on the rocks between high and low water mark, in very large abundance. The swamps and funken lands might be easily drained, and afford a rich fat soil. The soil of the interior country is represented as being excellent, and well adapted both for tillage and pasture. Where the soil is properly prepared for receiving the seed, it is said to be favourable for the growth of wheat, rye, barley, oats, peas, hemp, and flax, and for the production of almost all kinds of culinary roots and plants, Eng-
lish

lish grass, and also for Indian corn of short stalk. Kennebeck is much improving in apple-orchards. Hops are the spontaneous growth of the country. Peaches are scarcely known; but plums, small cherries, small pears, grapes, raspberries, gooseberries, currants, blackberries, and cranberries, are among the wild fruits of Maine. This country is uncommonly good for grazing, and large stocks of neat cattle may be fed in it both summer and winter. It abounds in white pine and spruce trees, suitable for masts, boards, or shingles; and maple, beech, red, white, and grey oak, and yellow birch, may be considered as the principal productions of the country. The moist land produces fir, which yields a balsam that is much prized. Here are also elms, poplars, and ash trees; also bass, horn-beam, butter-nut, balm of Gilead, and hemlock trees. Upon the whole, the district of Maine may be regarded in the three following divisions of it; the *first*, comprehending the tract lying E. of Penobscot river; the *second*, and best tract, lying between Penobscot and Kennebeck rivers; and the *third*, first settled, and at present most popular, W. of Kennebeck river. The climate in this district, as well as in every part of North America, is colder than is the same degree of latitude on the eastern side of the Atlantic. The weather is more regular here in the winter than it is in the southern states. Frosts commence sometimes in September, and always before the middle of October; the severe cold begins about the middle of December; and spring opens in the close of March. Of late the winters in this country are more moderate, and less snow has fallen than twenty years ago.

From the different rivers of this country water may be drawn for mills and all water works; and its rivers furnish plenty and variety of fish. The salmon fishery, in the bays and around the islands, has of late years become a considerable object to the inhabitants. The animals of this district were formerly deer, and moose of a large size; but there are now few to be seen. The fox, bear, wolf, beaver, &c. are found here. Cattle and horses are easily reared in this country; and the sheep, on the Kennebeck river, are larger than those in Massachusetts proper, the mutton is of higher flavour, and the fleeces are much heavier. The rattlesnake is the only poisonous serpent in this district, and is rarely seen. Birds, though increasing, are not numerous.

The manufactures and commerce of this country are in an improving state. From the first settlement of Maine till the year 1774 or 1775, and even in some places to a later period, the inhabitants neglected agriculture and generally followed the lumber trade; but when they found that Indian corn, rye, potatoes, and flax grew in their fields, and afforded an immediate profit, they applied to the cultivation of the soil; and they now raise a sufficient quantity of corn and other grain for their own consumption; and they export from the Kennebeck, either in cattle or other articles, more than they import. Their wool and flax are very good; hemp has been lately cultivated with success: and almost every family manufacture wool and flax into cloth, and make utensils of husbandry sufficient for their own use. The principal exports of this country consist of various kinds of lumber, such as pine-boards, ship-timber, and almost every species of split timber manufactured from pine and oak, which are exported from the various harbours in large quantities. Dried fish also furnishes an article of export, and also pickled fish, such as salmon, shad, &c. Mountain and bog-iron ore are found in some parts, and works have been erected for its manufacture. A spirit of literary improvement has been lately excited in this district. Bowdoin college in Brunswick is in a prosperous state. (See COLLEGE.) Academies have been incorporated by the legis-

lature in Hallowell, Berwick, Fryeburg, Bath, Hamden, and Machias, and endowed with grants of the public lands; and another has been instituted at Portland. Town schools are also maintained in most of the towns and in many of the plantations.

The people of this district are distinguished by no peculiar features from their neighbours in New Hampshire and Vermont; but they are, like them, a brave, hardy, enterprising, industrious, hospitable people. The prevailing religious denominations are Congregationalists and Baptists; and there are a few Quakers, Methodists, Episcopalians, and Roman Catholics. The remains of the Penobscot tribe are the only Indians who reside in this district: they consist of about 100 families, and live together in regular society, at Indian Old Town, which is situated on an island of about 200 acres, on Penobscot river, just above the Great Falls. They are Roman Catholics, and conduct their worship in an orderly manner and without molestation. The constitution of Maine is the same with that of the Massachusetts, both being incorporated under one government. In the district of Maine are large tracts of land belonging to the state, called the Eastern lands. Of these lands the commonwealth have sold as much as has brought into the treasury a net balance of 269,005*l.* 8*s.* 2*d.* Exclusive of these lands, that have been sold, tracts for the encouragement of literature and other useful and humane purposes have been granted to the amount of 431,000 acres.

The first attempt to settle this country was made in 1607, on the W. side of Kennebeck river, near the sea: but this proving unsuccessful, attempts for this purpose were not renewed till between the years 1620 and 1630. In 1635 sir Ferdinando Gorges obtained a grant from the council of Plymouth of the tract of country between the rivers Piscataqua and Sagadahok or Kennebeck, and up Kennebeck so as to form a square of 120 miles: and sir Ferdinando is supposed to have first instituted government in this province. In 1639 Gorges obtained from the crown a charter of the soil and jurisdiction, containing as ample powers as were ever granted by the king of England to any subject. In this year he appointed a governor and council; and government was administered in this form until the year 1652, when the inhabitants submitted to the Massachusetts, and in 1691, by a charter from William and Mary, the province of Maine, and the large territory eastward, extending to Nova Scotia, was incorporated with the Massachusetts Bay; since which time it has been governed and courts held as in other parts of Massachusetts. Several proposals have been made for separating this district from the Massachusetts; the last was made in 1802; but the legislature have not interfered in the business. Such, however, are the rapid settlement and growth of this country, that the period when this contemplated separation will take place, is probably not far distant. Morfe's Geog.

MAINE-Port, in *Ecclesiastical Antiquity*, a small tribute, commonly of loaves of bread, which in some places the parishioners pay to the rector of their church, in recompence for certain tithes. Cowell.

MAINIS, in *Ichthyology*, a name used by Aristotle, Athenæus, and others of the old Greek writers, for the fish now called the *mana*, *menerela*, and *menola*. It is a species of the sparus, and is distinguished from all the other species of that genus, by having four large teeth, and a variegated body, ornamented with a black spot in the middle of the sides. This is the fish the Narbons call *jafile*. See SPARUS *Mana*.

MAINLAND of Shetland, or Zeland, in *Geography*, the principal of the Shetland islands, situated in the Northern ocean.

MAINLAND.

ocean. It extends about sixty miles in length from north to south, and in some places is upwards of twelve in breadth. The whole of this island may justly be regarded as a series of promontories, every part of it being intersected by small arms of the sea. Hence scarcely a spot is to be found more than three miles distant from the shore. The coast is generally bold and rocky, but the numerous bays with which it abounds form safe and commodious harbours for the shipping which have occasion to frequent it. The interior presents to the view many interesting scenes, partaking both of the tranquil and of the wild. The latter, however, chiefly predominates; and while spots of cultivated retirement are comparatively few, the romantic beauties of simple nature are displayed in abundance and variety. Numerous hills diversify the face of the country, and traverse it in different directions. Of these the most lofty is called Rona's hill, or Mons Ronaldi, and is situated in the parish of North Mavean. In the statistical work of sir John Sinclair, it is stated to rise 3944 feet perpendicularly above the level of the sea, but Dr. Edmonston seems to think its height does not exceed 2000 feet, if indeed it is actually so much. The view from the summit of this hill in clear weather is splendid and magnificent in the extreme. The cluster of islands scattered beneath, and curiously divided by the ocean, afford a prospect infinitely diversified and agreeable. On the highest eminence there is a house constructed of four large upright stones, and two which serve as a covering for the roof. It is called a watch-house, and was probably used in remote ages to give notice of any approaching danger. A pyramidal tower of small stones is erected on the top of this hill, which is a land mark to the fishers all round the country, and generally the first land descried by ships if they fall to the west of the island, as they approach it from the north.

The climate of the Mainland is extremely variable and damp, although by no means generally unwholesome to the inhabitants. Spring can scarcely be said to commence until April, and there is but little general warmth before the middle of June. The summer usually terminates with August. Autumn is a very uncertain season, and winter commences as early as the beginning of October. The soil of Mainland is no less various than the climate. The arable land lies chiefly on the coast, and bears but a small proportion to the waste and uncultivated parts, though its productiveness might be greatly increased by labour and exertion. The only grains sown are a species of barley, known by the name of beer or big, and a small kind of black or grey oats. Potatoes are raised in considerable quantity. The manure chiefly in use is sea weed, sometimes alone, but oftener mixed with earth or dung from the *byres*, or cow-houses. Though lime-stone is sufficiently abundant as well as the means of burning it, it is seldom employed. This is a matter of deep regret, as on those spots where it has been tried, the increase of fertility has much exceeded expectation. In consequence of this inattention of the natives to the management of their grounds, the vegetable products of the island are far from being adequate to its consumption. Hence the necessity of importing considerable quantities of grain from other more prolific districts. Carts are scarcely known here, for the best of all reasons, that there are no roads made by art in any part of the country. The construction of their ploughs is extremely rude, being in all probability of the same description with those used in ancient times over the whole of Europe. They consist of a crooked piece of wood bent (naturally) almost to a right angle, forming the beam, to which is fixed an oak staff about seven feet long, which is very pliable, and yields to the pressure of the driver's hand when he wishes to deepen the furrow. The coulter

stands almost even up and down, and is never of sufficient length. A square hole is cut through the lower end of the beam, wherein the mercial, a piece of oak about twenty-two inches long is introduced. The furrow is rendered deep or shallow by driving a wedge below or above the mercial, on the outside of the beam. The man who holds or governs the plough walks by its side, and directs it by a tilt or handle. The driver, or guide, precedes the oxen, usually four in number, and draws them along by means of a rope fastened to their horns. The other agricultural implements correspond to the mean construction of the plough. Owing to the limited extent of many farms the ground is very often dug with spades. Seeding time commonly begins here about the middle of March, but it varies in different parts of the country. It is earliest in the parishes of Tingwall, Whitenefs, Weefdale, and Dunrofsnefs, where the soil is drier than in most other places, and has a limestone bottom. With respect to the period of harvest, the seasons are so various, as to render it impossible to say any thing precise concerning it, being sometimes over by the middle of September, and at other times scarcely finished in November. When it happens to be thus late, the crop affords little sustenance to man, and is only valuable as fodder for the cattle. The whole lands of the island nearly remain without inclosures. The cultivated lands are divided, but the extensive hill pastures remain in common. For the division of these many proposals have been offered, but the attempt has hitherto proved abortive, and indeed it must be confessed, that upon the present Shetland system of agriculture such an event would be attended with very little advantage, unless proper fences were constructed, or shepherds appointed to confine the sheep or cattle within any prescribed boundaries. It is somewhat remarkable that not a single tree is to be seen in the whole island, and still more extraordinary that no proper attempt has been made to ascertain whether the climate will permit their growth. Certain it is, however, that in early ages they must have reached considerable perfection here, as many decayed trunks of large trees are often found among the bogs and mosses.

With respect to the domestic animals of the Mainland of Shetland, it is well known they are the smallest of any in the British dominions; a circumstance doubtless the consequence of their scanty supply of food, and the total disregard manifested by the inhabitants for the improvement of their native breed. Some attempts have indeed been made by a few individuals to introduce breeds from more southern countries, but the climate of this northern region has been found unfavourable to the animals of warmer latitudes. The number of horses reared here is very considerable. They are generally about nine or ten hands high, full of spirit, and better calculated to endure fatigue than much larger horses. They are usually denominated Shetland ponies, and are evidently sprung from the Norway horse. These animals are never put into a house, either in summer or winter, nor do they receive any food but what they gather from the ground. The horned cattle are greatly inferior in every point of view to those of Orkney or the Western isles of Scotland. The cows give very little milk; but as a great portion of the rents was of old paid in butter, now converted into money, it seems reasonable to conclude either that cows were formerly more numerous here, or produced greater quantities of milk than at present. Cheese is seldom made, and indeed a great many of the farmers are yet ignorant how to manufacture it. Their method of making butter is peculiar to the Shetland islands: Red-hot stones are thrown into the churn just at the time when the butter is about to separate from the serum, after which the churning is continued till the butter separates,

MAINLAND.

separates, and rises to the surface. The number of cattle in the whole island is estimated at about 40,000 head. Swine are bred in great plenty, and are particularly remarkable for the extreme shortness of their backs. The sheep are of different breeds, two of which produce a very fine wool, manufactured by the inhabitants into stockings. These animals feed at large on the hills, each proprietor having a peculiar mark upon them, to distinguish whose property they are. The alertness of the inhabitants, and the sagacity of their dogs, in tracing and separating their own flocks from the general flock, are subjects of wonder to every stranger who visits the Mainland.

In this island there are very few goats, and no hares or foxes: and in general few wild or ravenous quadrupeds of any kind. Tame and wild fowls, however, exist here in great abundance, particularly the latter; some of which are extremely destructive to the young lambs. By the police of the country, every person who kills an "erne" is entitled to a reward of 3s. 4d.: for a corbie or raven he receives 3d.; and for a crow 2d. These rewards are paid by the commissioners of the land-tax, upon seeing the heads of the fowls that have been killed. The number of migratory birds which frequent the rocks on the coast is immense, and though they build their nests on the brink of precipices seemingly inaccessible, the inhabitants, disregarding the danger of the attempt, plunder them both of their eggs and young.

The mineralogy of this island, though of little importance for the purposes of common life, presents many interesting objects of contemplation to the geologist. Rocks of primary and secondary formation can be distinctly traced in most places, and offer a variety of satisfactory illustrations of the Neptunian theory. Volcanic appearances are extremely uncommon, and purely adventitious. The hills chiefly run in ridges, or appear conical and detached. Except in the parish of North Haven, there are few of them of the rugged or abrupt kind. Sumburgh-head, a bold and lofty rock at the southern extremity, is composed entirely of indurated sandstone, and the same material appears to form the coast along the greater part of the peninsula of Dunrosness. The cliffs of Coningsburgh are composed chiefly of micaceous schistus, as are likewise the hills which bound the valley of Quarf. The coast of North Haven presents a grand display of natural beauties, the rocks assuming a variety of curious forms from the excavations of the sea. Rona's-hill, on the northern portion of this parish, is an immense mountain of granite, and all the rocks on its western boundary are composed of the same fossil. About a hundred and fifty feet from the shore, here stands a very lofty rock or holm, the sides of which are perfectly mural. It is called Maiden Sherie, and has never yet been trod by human foot, the black gulls maintaining it in exclusive and unmolested possession. Near Lerwick, the rocks are a mixture of sandstone and breccia. Limestone is found in considerable abundance near Coningsburgh. Beds of the same mineral stretch along Weefdale, as well as throughout the whole valley of Tingwall; in all which places it is wrought, and forms an article of exportation. Some strata of iron ore have likewise been discovered in different parts of the country, and attempts have even been made to open mines, but none of them have yet proved successful.

The only remains of antiquity worthy of notice are what are called Picts'-houses, and these abound in every district of the island. They are usually about fourteen feet high, but differ in the extent of their circumference at the base. The interior consists of several cells or apartments, one of which, situated in the centre, is of much larger di-

mensions than any of the others. All of them are constructed of large flat stones, without any cement or mortar.

The only villages in the Mainland are Lerwick and Scalaway. The latter is the more ancient of the two, but the former the more considerable. Lerwick is situated on the Bressay sound, long the general rendezvous of the Dutch fishing-vessels; and, being the seat of the courts of justice, is esteemed the capital of the Shetland islands. See **LERWICK** and **SCALAWAY**.

As to the inhabitants of this island, the inferior classes are usually represented as depressed and miserable. Both the men and women are, generally speaking, well proportioned, of fair complexion, and an agreeable expression of countenance. Great attention is paid by them to the growth of the hair, which is valued in proportion to its length. The peasantry are noted for their curiosity and acuteness; but the acquisition of useful knowledge is seldom the object of their inquiries. Some of them, however, have excelled in the mechanical arts by the mere force of natural genius alone, unaided by education or example. Dr. Edmonston mentions a blacksmith, who was completely master of clock and watch-making in all its branches, although he had probably never witnessed any part of that delicate manufacture. Small as their country is, a considerable variety of manners and habits is discernible in different districts; the inhabitants of some parishes being remarkable for their gaiety, and others no less so for the gravity and sobriety of their deportment. Suspicion, indolence, and servility are qualities too generally diffused among them, the consequence, no doubt, of the immemorial operation of feudalism. Belief in witchcraft, fairies, and the efficacy of alms, is also still prevalent over the whole island, and freemasonry is universally considered as conferring upon its votaries the rare faculty of detecting theft.

The manufactures carried on here are but few, and these in general imperfectly conducted. The knitting of worsted stockings, caps, and gloves by the women, is among the most ancient. Shetland hosiery has long been held in high repute, and formed a considerable article of exportation. The demand for it has of late years, however, considerably diminished even in the British islands, and scarcely any of it now reaches the continent. A sort of coarse cloth or clath is wove here by individual weavers, as well as blankets for home consumption. Kelp is now a staple manufacture, and at Lerwick there is both a straw and a rope manufactory. The chief employment of the inhabitants, however, and the principal source of their wealth, are the fisheries established on their coasts, which abound with herring, cod, tusk, and ling. The Dutch formerly owed to their Shetland fisheries in no small degree the elevated station their country held during the two last centuries, among the nations of Europe. Almost all the land proprietors here are engaged in this traffic, and as more profit arises from it than from their estates, their lands are made subservient to its prosecution. Hence in some measure proceeds the low condition of husbandry, and the dependent obsequiousness of the common people. Every laird endeavours to establish on his estate as large a number of persons as he possibly can, as he thereby obtains a greater number of fishermen. Farms are therefore divided and subdivided; and waste lands allotted to all who are willing to settle on them. The facility of obtaining possessions encourages marriage, and as a consequence, the population of the island is much greater than it can support. The young men being burdened with more numerous families than they can well support, find themselves speedily involved in difficulties. Having no leases of their possessions, and all the fish they take belonging to the landlord at a fixed price, a state of ab-

ject dependence on their superiors may be reasonably concluded to exist; and it actually does exist over the whole of Shetland. The chief exports from the island are, fish, oil, butter, beef, hides, tallow, stockings, calf, and rabbit-skins. The imports consist of the luxuries, and even necessities of life, particularly cloth and corn; the whole island, as already hinted at, not producing grain sufficient to supply the inhabitants more than eight months in the year. For a more particular account of the Mainland, and a view of its general history, see the article *SHETLAND Isles*, also "A View of the ancient and present State of the Zetland Islands," by Arthur Edmonston, M.D. 2 vols. 8vo. 1809.

MAIN-MORTE, a term in some ancient customs, still obtaining in Burgundy, signifying a right which the lord has, on the death of a chief of a family that is *main-mortable*, of taking the best moveable in the house; or, in default of that, the right hand of the deceased was offered him, in token that he could serve him no longer. See **MORT-MAIN**.

MAINO JASON, DEL, in *Biography*, an eminent Italian lawyer, born at Pefaro in 1405, was sent to Pavia to study the law, having received the elements of a good education in his native place. Free from the constraint of parental observation, he applied himself more to the gaming table than to those pursuits which were intended to fit him for future life. By this line of conduct he was soon reduced to a state of almost absolute indigence. The animadversions of his father, together with his own sufferings, effected such a change in his mode of living, that he became the admiration of his superiors on account of his learned acquisitions. In 1467 he was elected a professor at the university of Pavia, and continued there with high reputation till the year 1485, when he accepted a professorship at Padua. In 1488 he removed to the university of Pisa, to which the republic of Florence invited him, on a very liberal salary. After this he resumed the professor's chair at Padua, where his reputation was so high, that he is said to have had three thousand auditors. Besides the duties of his office as teacher, he transacted much public and important business with accuracy and fidelity. In 1492 he was sent by the duke of Milan to do homage to pope Alexander VI., on which occasion he pronounced an oration that was afterwards printed. He was, in 1494, sent to compliment the emperor Maximilian on his marriage, and on this occasion he was rewarded with the title of cavalier and count-palatine: and next from Ludovico, duke of Milan, he obtained the rank of patrician, and honorary post of senator. Lewis XII. of France, attended by five cardinals, paid a visit to his school; Jason, in introducing his majesty, humbly requested him to enter first, to which Lewis replied, "I am no king here," and obliged the professor to precede, he being entitled to the chief respect among his scholars. After the lecture the king embraced Jason with the utmost cordiality, and in the course of a familiar conversation, he hinted to his majesty, that he might favour him, by mentioning his name to the pope as not disqualified to wear a cardinal's hat. He was, however, unable to attain to the object of his ambition, and continued to hold his office as professor till the year 1511; after this he fell into a state of dotage, in which he continued till he died in 1519. This gentleman was esteemed one of the greatest masters of jurisprudence in his time, and is mentioned by Alciatus among the five jurists who alone deserve to be read. *Gen. Biog.*

MAINOUR, MANOUR, or Minor, Fr. *Mainoeuvre, a manu*, in *Law*, signifies the thing that a thief takes away, or steals.

Thus, to be taken with mainour, is to be taken with the

thing stolen about him. If the defendant were taken with the mainour, and so carried to court, in ancient times they would arraign him on the mainour, without any appeal or indictment. But this proceeding was taken away by several statutes in the reign of Edward III., though in Scotland a similar process remains to this day. See **ATTACHMENT of the Forest**.

MAINPERNORS. See **MAINPRISE**.

MAINPRISE, compounded of the French *main, hand*, and *pris, or prins, taken*, the taking or receiving a man into friendly custody, who otherwise might be committed to prison; upon security given for his forthcoming, at a day assigned.

They who thus undertake for any one, are called *mainpernors*, because they receive the person into their hands; whence also comes the word *mainpernable*, denoting the person who may be thus bailed. F. N. B. 250. 1 Hal. P. C. 141. Coke on bail and mainprise, c. 10. See **BAIL**.

The writ of mainprise is a writ directed to the sheriff, (either generally, when any man is imprisoned for a bailable offence, and bail hath been refused; or specially, when the offence or cause of commitment is not properly bailable below), commanding him to take sureties for the prisoner's appearance, and to set him at large. Mainpernors differ from bail, in that a man's bail may imprison or surrender him up before the stipulated day of appearance. Mainpernors can do neither, but are barely sureties for his appearance at the day: bail are only sureties, that the party be answerable for the special matter which they stipulate: mainpernors are bound to produce him to answer all charges whatsoever. Coke, *ubi supra*, c. 3. 4 Inst. 179.

MAINTAINERS, are those that maintain or second a cause depending between others, by disbursing money, or making friends for either party, &c. not being interested in the suit, or attorneys employed therein. Stat. 19 Hen. VII. cap. 14. See **MAINTENANCE**.

MAINTENANCE, MANUTENENTIA, an unlawful maintaining, or officious intermeddling in a suit between others, by assisting either party with money or otherwise, to prosecute or defend it. Hawk. P. C. 249.

The word is metaphorically taken from the succouring a young child, that learns to go by one's hand; but it is used in the bad sense in some of our statutes.

By the Roman law, it was a species of the *crimen falsi* to enter into any confederacy, or to do any act, to support another's law-suit, by money, witness, or patronage. A man may, however, maintain the suit of his near kinsman, servant, or poor neighbour, out of charity and compassion, with impunity; otherwise the punishment by common law is fine and imprisonment; and by stat. 32 Hen. VIII. cap. 9. a forfeiture of 10*l.* See **BARATRY** and **CHAMPARTY**.

There lies a writ against a *maintainer*, called a writ of *maintenance*.

MAINTENON, FRANCES D'AUBIGNE, in *Biography*, celebrated in the history of France as well for her great accomplishments, as for the singularity of her fortunes, was born in a prison at Niort in the year 1635. In this solitary abode her father, Constant d'Aubigne, was confined for some political offence. Here he and his infant daughter remained during the first three years of her life, at which time her father, having obtained his liberation, carried her with his wife and son to Martinique. She was indebted to her mother for an excellent education, that was unquestionably the base of her future elevation. On the death of her father, in 1647; the family returned to France, when the young lady was taken under the care and protection of madame de Villette, who infused into her mind those principles of the Calvinistic faith

faith to which her father had been zealously attached. Her mother, who was a strict Catholic, took great pains in converting her to her own opinions, which she effected. They removed to Paris, where the mother very soon died, leaving her children in the greatest indigence. Frances, from this circumstance, and from the severity of some other near relations, was induced to give her hand to the famous Scarron, who was not young, and who from disease was in a state of decrepitude. She accepted this union, it is said, rather than the other alternative which he offered her, of paying her portion to be received into a nunnery. The house of her husband was frequented by many men of rank and wit, and the young wife attracted general admiration by the graces of her person, and the elegant charms of her conversation. In this dangerous situation she conducted herself in such a manner, that her virtue was unfulfilled and unsuspected. Her intimacy with the celebrated Ninon de l'Enclos did not in the least injure her reputation, and the testimony of her friend, in favour of her morals, has been admitted as good evidence. Scarron died in 1660, and his widow was again left in a state of indigence: for a short time, and after much sollicitation, she obtained from the queen-mother the pension which her late husband had enjoyed; but at the death of the queen, she was again destitute. At this time a proposal was made to her to go to Lisbon to undertake the education of the children of a Portuguese princefs. She gladly listened to the proposal, and just before her intended departure she waited upon the king's mistress, madame de Montespan, who, struck with the elegance of her manners, and the graces of her conversation, told her she must not think of quitting France. She immediately applied to Lewis XIV. for a pension to be settled on the forlorn widow, to which the monarch angrily replied, "shall I never hear of any thing but the widow Scarron." Indeed, she, replied the favourite, "you ought long since to have ceased to hear of her." The pension was, however, granted, and she remained in France. Madame de Montespan, who had now strong claims to her gratitude, conceived such an esteem for her, that she entrusted her with the secret of the children which she had by the king, and placed them under her care. At first she had the mortification to find that Lewis was not friendly to her. Her talents, however, were such as time would bring into notice, and she gradually rose into favour, and was chosen by the monarch himself to attend his eldest son, by madame de Montespan, the duke of Maine, to Bareges, for the recovery of his health. This situation engaged her in a direct correspondence with the king, a circumstance that operated very strongly in her favour: he augmented her pension, and made her liberal presents. Her serene and equal temper, and rational conversation, gradually gained upon Lewis, till at length she became his confidential friend. Her age, which exceeded that of the king, the moderate share of personal attractions which she retained, and the strictness of her religious principles, seem to have been sufficient assurances of the innocence of their connexion. Madame de Maintenon has been charged with ingratitude towards her benefactors, who was now discarded from the court, but she has found advocates who have fully vindicated her from the suspicion. Her situation with Lewis was, for some years, equivocal: she was an acknowledged favourite, but to what extent was not known; there was a singular mixture of devotion and gallantry in the correspondence carried on between the king and his female friend, and in allusion to this, Voltaire observes; "This strange commerce of tenderness and scruple on the part of the king, of ambition and devotion on that of the new mistress, seem to have lasted from 1681 to 1686, which was the epoch of their marriage. This union was

never doubted, though never openly acknowledged at court, and madame de Maintenon preserved that name while she was regarded and honoured as a queen. She always conducted herself with extreme good sense and moderation; was very reserved in asking favours for herself and family, and in these respects she formed a striking contrast to preceding favourites. Excessive caution, amounting to timidity, which appeared to extinguish every warm and generous emotion, was a characteristic feature of her conduct. She devoted herself entirely to the king, which she found to be a task that rendered her elevated situation most painful and joyless." "What a punishment," said she, to a near relation, "to be obliged to amuse a man who is no longer amiable." That her feelings on this subject were extremely acute, is evident from an extract of a letter to an intimate friend: "Why," says she, "cannot I give you my experience? why cannot I make you sensible of the wearisomeness to which the great are a constant prey, and the labour they undergo to fill up their days? Do not you see that I am consumed with melancholy, in a condition which it was scarcely conceivable that I should ever have attained." She attempted to supply the void which she felt by the practices of a minute and scrupulous devotion, and she inspired the king with a similar taste; but, at the same time, she was not insensible to the ambition of ruling, and often exerted her influence when she was not suspected of having an opinion. But she found it necessary to use the utmost circumspection, for the king would not bear a rival; and if he suspected any design to controul his will, he was apt to determine on the contrary. As his infirmities increased, she became more and more necessary to his existence, and is said to have shared with his confessors the possession of his mind to the last hour. She employed a considerable portion of a scanty income in deeds of charity and benevolence, but her most splendid work was the establishment at St. Cyr, near Versailles, including a religious community, and an institution for the gratuitous education of 300 young ladies of quality. For this she engaged Racine to compose the sacred dramas of Esther and Athaliah, in which the young ladies acted their parts so well, in the first representation, that she determined they should not appear in the characters again. On the death of the monarch in 1715, madame de Maintenon retreated to this peaceful mansion, thenceforth resigning all concern with the great and political world, acting in the laudable duties of the directress of the institution, and instructress of the young people educated in it. She was occasionally visited by a few particular friends; among whom her former pupil, the duke of Maine, was always received with the expressions of truly maternal affection. She lived to the great age of eighty-four, and died at St. Cyr in 1719. She is known in the literary world by a collection of letters in nine vols. 12mo. which were published in 1756; these are well written, and contain many things worthy of attention. Gen. Biog.

MAINTENON, in *Geography*, a town of France, in the department of the Eure and Loire, and chief place of a canton, in the district of Chartres; nine miles N. of Chartres. The place contains 1605, and the canton 13,369 inhabitants, on a territory of 205 kilometres, in 21 communes.

MAJO, FRANCIS, or CICCIO DE MAJO, in *Biography*, a Neapolitan composer of the first class, who flourished from about the middle of the last century to 1774: his works are few, as longevity was not allowed him. Metastasio's *Artaserse* in 1762, *Antigono* in 1769, *à Didone Abbandonata*, and *Alessandro nell'Indie*, both these last in 1774, are all his dramatic works with which we are acquainted. He was in very high favour at Naples and Rome in the year 1770,

when natives as well as foreigners were eagerly collecting his opera airs composed for great singers; of which airs the style was noble, the accompaniments elegant and interesting, without disturbing or overpowering the voice, and each air is a more complete whole, perhaps when detached for occasional use at concerts, than those of any other great opera composer with whose productions we are acquainted.

M. Laborde's character of this charming composer is very just; but his dates are far from accurate. Artaxerxes was not the first opera which he composed, but Riccimero, for the theatre Delle Dame at Rome in 1759; and in 1763 his Demofonte was performed at the Argentina theatre in the same city.

M. Laborde tells us, that though he had often gone the rounds of the great theatres in Italy, he never would quit his country; but in 1764, we find by Metastasio's letters to Farinelli, that he was at Vienna in his way to Manheim, where he was engaged to compose an opera.

Farinelli seems to have given him a letter of recommendation to the imperial laureat, in the answers to which we may form some judgment of the private character of this gifted man.

Metastasio, in his first letter to Farinelli, in which Ciccio de Majo is mentioned, says, "Our dear Majo has been arrived some time, but I have seen him but once, and then only for a short time. I received him with all that affection which I cannot help bestowing on persons beloved by you, and whose merit is universally known. Nor shall I neglect any opportunity of serving him, as far as the august circumference of my limited faculties shall extend. The best of it is, that he not only never comes near me, but leaves me in perfect ignorance of the hiding place where he has hitherto amused himself here, during the leisure in which he has hitherto lived. Perhaps some ancient sparks have rekindled the extinguished conflagration, and the poor soul will be involved in the flames and smoke which formerly, as I am informed, scorched and confounded him."

In another letter of the same date, Metastasio says, "Your most amiable de Majo generously gives me credit for wishing to serve him, but hitherto has absolutely avoided putting my zeal to the test. A man of his merit, and your friend, would have a right to dispose of me at his pleasure. But he, who is no fool, knowing perhaps the little extent of my power, is unwilling to expose me to the shame of confessing it. I am unable to inform you whether he has been caught in the old net. I never frequent the woods which expose him to such danger, and have never been able to examine him; as during his long residence on the banks of the Ister, I have only had the pleasure of seeing him two or three times, at most. Indeed his continuing so constantly invisible, and remaining here so long, without any apparent motive, seems to favour your conjectures. If he is at sea, I wish him a prosperous gale; if such a wish is not inconsiderate: as the felicity of a navigation depends much on the cause for which we embark; and I never wish my friends to be possessed of such an inconsiderate courage."

And in a third letter, he says, "Our ardent and languid Majo, stimulated by his friends and by his duty, is at length set off for Manheim, where he is engaged to compose an opera for the elector palatine. With what heart he has left the banks of the Ister, enamoured turtles say!"

This exquisite composer and tender hearted swain, who had been possessed of the world, would have *lost* it all for love, with as good a grace as Mark Antony, died in 1771. The last opera he composed, was *Didone Abbandonata*, for Venice, in 1770.

Majo Bamba, in *Geography*, a town of Peru, in the jurisdiction of Chacapoyas.

MAJOR, JOHN, in *Biography*, was born at North Berwick, in Scotland; he laid the foundation of a learned education in his own country, and afterwards studied some time at Cambridge and Oxford. In 1493 he went to Paris, where he prosecuted his studies at different colleges; in 1505 he was made doctor of the Sorbonne, and in 1519 he returned to his native country, and was elected professor of divinity at St. Andrews, where the celebrated Knox was one of his pupils. He afterwards attained to the office of provost of that university, where he died at the age of seventy-eight, in the year 1547. He was a voluminous writer in metaphysics and logic, but his works on these subjects have long been forgotten, and he is now remembered and quoted only as the historian of his own country. His main work is entitled "De Gestis Scotorum," in six books, first published at Paris in 1521, which bring down the history from the earliest periods to the year 1495. He rejects the fictions of antiquarians relative to the remote history of the nation, and reduces the list of its early kings. He is a strenuous advocate for the independence of his country, and speaks freely of the power of the people and the prerogatives of parliament; he is an enemy to public abuses, and speaks with decision of the acts of the kings whose conduct he never scruples to condemn. Bishop Leslie says of his history "Veritatis ubique quam eloquentiæ studiosior." Gen. Biog.

MAJOR, JOHN DANIEL, a physician and naturalist, was born at Breslau, in August 1634. Having studied for some time at Wittemberg, he visited several universities of Germany and Italy, and graduated at Padua in 1660. He returned to Silesia through Austria; but, after a short visit to Breslau, he settled himself at Wittemberg, where he married the daughter of the celebrated Sennertus in 1661, who died in child-bed in the following year. This interruption of his domestic happiness impelled him to leave Wittemberg, and he settled at Hamburg, where he undertook the office of superintendent of the treatment of the plague. The success of his practice obtained for him, in 1663, the honour of being enrolled among the members of the Academia Naturæ Curiosorum, under the name of Hesperus, and likewise an invitation, through the Russian consul at Hamburg, to settle at that court, with the appointment of first physician: but he declined this offer, from a dislike to quit his own country, and to reside among a people, whose language and manners were so widely different from those with which he was familiar. In 1665, he was appointed professor of the theory of medicine in the recently established university of Kiel; and he was afterwards honoured with the appointments of professor of botany, and director of the botanic garden there. These offices called forth the exertion of his utmost zeal, in support of the reputation and utility of the rising university, which he essentially contributed to establish by his travels and researches, and by the valuable collections with which he enriched it. By these exertions his own reputation was likewise extended, so that in 1693, he was called to Stockholm by Charles XI. to superintend the treatment of the disorder of his queen. But he was himself attacked with disease, while in that capital, which terminated his life on the third of August, in that year.

Major was indefatigable in his researches, both in natural history and medicine, and was the author of a considerable number of publications: Eloy has enumerated the titles of upwards of twenty works, exclusive of a number of academical dissertations. The principal subjects of the former were,

were, petrifications or fossils, renal calculi, transfusion, anatomy, botany, artificial medicated baths, &c. Eloy Dict. Hist. de le Méd.

MAJOR's Bay, in *Geography*, a bay of the island of St. Christopher. N. lat. 17° 20'. E. long. 62° 22'.

MAJOR, in *Law*, a person who is of age to manage his own affairs. See AGE.

By the civil law, a man is not a major till the age of twenty-five years; in England, he is a major at twenty-one, and in Normandy at twenty.

MAJOR, in *Logic*, is understood of the first proposition of a regular syllogism.

It is called *major*, because it has a more extensive sense than the *minor* proposition, as containing the principal term. See PROPOSITION.

MAJOR, in the *Art of War*, a name given to several officers of different qualities and functions.

MAJOR-general. See GENERAL, *Major*.

MAJOR of a *Brigade*, either of horse or foot, is he who receives orders, and the word, from the major-general; and gives them to the particular majors of each regiment. See BRIGADE-major.

MAJOR of a *Regiment* is an officer, whose business is to convey all orders to a regiment, to draw it up, and exercise it, to see it march in good order, to look to its quarters, and to rally it, if it happen to be broken in an engagement, &c.

The major is next in subordination to the lieutenant-colonel, and generally promoted from the eldest captain. He is the only officer of a regiment of foot, who is allowed to be on horseback in the time of service; but he always rides, that he may speedily get from place to place, as occasion requires.

The major of a regiment, either of foot or of horse, ought to be a man of honour, integrity, understanding, courage, activity, experience, and address; he should be skilled in arithmetic, that he may keep a detail of the regiment in every particular, and also in horsemanship; and he should be well acquainted with all military evolutions, that he may be competent to the exercise of his duty in the instruction of others.

MAJOR of *Artillery* is the next officer to the lieutenant-colonel. In the field he receives daily orders from the brigade-major, and communicates them, with the parole, to his superiors, and then dictates them to the adjutant.

The whole detail of the corps rests with this officer; to him all the non-commissioned officers are subordinate, as his title of serjeant-major imports, and to him they communicate an account of every circumstance that regards the duty or the wants of the artillery and soldiers. This officer should be well acquainted with all the powers and evolutions of the artillery, and with every thing that pertains to the train of artillery, &c.

MAJOR of *Engineers*. See ENGINEER.

MAJOR, *Serjeant*, is a non-commissioned officer, subordinate to the adjutant, as he is to the major.

MAJOR, *Town*, is the third officer in order in a garrison, being next to the deputy-governor.

He ought to understand fortification, and hath charge of the guards, rounds, patrols, and centinels.

There are also aids-major, drums-major, and other officers; so called, on account of some seniority or prerogative that they have over the rest. See AID-major, and DRUM-major.

MAJOR, *Fife*, has the same authority over the fifers as the drum-major has over the drummers. He teaches them their duty, appoints them for guards, &c.

MAJOR *Helicis*, in *Anatomy*, a name given by Albinus to

one of the muscles of the eye, called by Santorini and others, *helicis musculus*. This author distinguishes it under the name *major*, from another muscle which he calls the *minor helicis*, and which Santorini calls only *fibræ musculares in plana helicis facie*, though it be a true and proper muscle.

MAJOR and *Minor*, in *Music*. See MAGGIORE.

MAJORAGIO, MARCANTONIO, in *Biography*, an Italian scholar of the sixteenth century, was born in a village of that name in the diocese of Milan. His father's original name was Conti, and he assumed the name of the place in which he settled, and to which he had been driven and reduced to poverty by the wars in Lombardy. The subject of this article was indebted to a relation for his education, whose cares he well repaid, by the diligence with which he pursued his studies. One of his preceptors was the famous Cardan, and such was his proficiency, that at the age of twenty-six he was appointed public professor of eloquence at Milan. He afterwards, on account of new wars, was obliged to go to Ferrara, where he improved himself in philosophy and jurisprudence. At the return of peace he resumed his station at Milan, and contributed greatly to revive the study of letters by restoring the practice of public declamations, by promoting the establishment of an academy, and by his attempts to found a public library. He died in 1555, at the age of forty-one. His works are numerous, consisting of orations, prefaces, poems, Latin and Italian, and tracts on various subjects. He employed his talents as a commentator on the works of Cicero and Aristotle. Bayle.

MAJORANA, in *Botany*, so called, says Ambrosinus, because it is cultivated with greater care (*majori curâ*) than other herbs; or because it has greater virtues and properties than are generally known; or because it is most powerful in the month of May; or because it agrees better with grown up persons (*majoribus*) than with infants. None of these derivations seems satisfactory. The plant however appears to be properly considered as the "*mollis Amaracus*" of Virgil, immortalized in those exquisite lines of the *Æneid*, book i. L 695—8, inaccurately and incompletely translated by Dryden, who seems to take the *Amaracus* for Myrtle. These lines are indeed, as has been observed, the despair of all Virgil's translators. See ORIGANUM.

MAJORCA, in *Geography*, an island of the Mediterranean, belonging to Spain. It is the largest of the Balearic isles, and reckoned to be about 55 English miles in length, and 45 in breadth; and separated from Spain by about 40 leagues of sea. It is almost wholly surrounded by a chain of mountains, of which an interrupted branch extends into the interior; those of Puig Mayor and Galatz are the highest and most considerable. The climate is temperate; the fresh breezes tempering the heat of summer, and on the eastern coast little cold is felt in winter; but the temperature varies in different situations. But though it is well sheltered on the north, some winds occur, which sometimes entirely destroy the plantations. The vallies are fresh and fertile, though without water. However, some large brooks spring from the vicinity of the mountains, and run through some parts of the island; and two small rivers, particularly the Riera, which rises under the ramparts of the capital. This island contains two cities, Palma and Alcudia, several small towns, and many hamlets. A Spanish author assigns to it two cities, 32 towns, a number of remarkable villages, 2001 farms, 1877 country houses, 10 castles or fortresses, 40 towers, where centinels are placed with fires during the night, to give alarm in case of danger, and 210 brooks or springs. The capital is Palma, or, as it is otherwise called, Majorca.

M A J O R C A.

The kingdom of Majorca, comprehending the ancient Iberian islands, or the Balearic and Pituyse, lost much of its ancient population in the year 1229 by the defeat of the Moors, and the carnage made by the Christians, in order to revenge the death of the celebrated viscount de Bearn, William of Moncade, and his brother. In the year 1301 the Jews, who had been driven from Spain on account of their exactions and unfury and settled here, were banished from the island. About the beginning of the 15th century, Majorca was afflicted with famine for 10 years, and its commerce declined with its population. In 1403 the river Riera carried away 1600 houses, and drowned 5500 persons. A similar catastrophe occurred in 1408 and 1444. These disasters were succeeded by a civil war. In 1475 the island suffered great devastation from the plague. By these and other occurrences the population of Majorca was much diminished; but in this state it furnished troops for a militia, raised in order to defend the coast against the incursions of the Barbarians. The nobility of Majorca was formerly considerable; and in the middle of the 16th century they engaged against the Africans, who endeavoured to invade the island. But after this epoch it enjoyed much internal tranquillity, though it never rose to that eminence, which it is said to have attained under the Moors. The number of inhabitants is now estimated at about 136,000 persons, among whom are reckoned 1050 secular priests, 1000 monks and hermits, 600 cloistered nuns, and 600 women voluntarily engaged in charitable institutions.

The agriculture of Majorca is in a flourishing condition. The mildness of the climate, and the fertility of the country, has given to the islands of this kingdom the name of the "Fortunate Islands." (Strabo, lib. iii.) The groves of orange trees produce excellent fruit, and the vines are loaded with grapes. The mountains in general are covered with trees of various kinds, as firs and holm-oaks, fit for carpenters and ship-builders; and the wild olives are abundant. The plains and vallies, which are well watered, exhibit the appearance of meadow ground. The flocks furnish a great quantity of the finest wool; and by the culture of mulberry trees, they feed a number of silk worms, whose produce serves not only for domestic use, but promises to afford an article of exportation. In some territories they cultivate several kinds of corn, and delicious figs, which are dried; in others they graze cattle. The plain between Felonice, Montuyri, San Juan, and Petra is considered as the granary of the isle. Corn, wine, oil, fresh and dried figs, and brandy, supply the wants of the interior. The eastern valley of Alcudia is very fruitful and rich. Grains of different species, honeycombs, olives, carobs, hemp, and every variety of fruits and herbs, are abundant. The valley of Soler is famous for its beauty and fertility, and is the pride of the islanders; and the canton of the mountains of Bagnabufar abounds in wine and flax, which are also produced in many other parts of the island. The Majorcans, however, are reproached with a lassitude injurious to their prosperity. They import as much as 50,000 fanegas of wheat to supply the consumption of 136,000 inhabitants, who possess a territory of 1234 square miles, which are supposed to be the extent of the island. The Majorcans manufacture a sort of coarse strong cloth for their own use, and a large quantity of corded woollen stuff, which is exported into Catalonia and the kingdom of Valencia. They have also looms for tapestry, blankets, and sashes, all in wool, exported to Malta, Sardinia, Valencia, and even to America. They manufacture silk in the island, and make several stuffs used by the inhabitants, as well as linen cloths, some of which are very fine. The

coarse canvas, which they fabricate for the use of the marine, is exported. They make brooms, paniers, and baskets, out of the leaves of the palm-tree, which are transported into Spain. These islanders have been famous for their inland work, and this branch of commerce is profitable. The wines of Majorca are excellent. The lightest and finest, though frisky and delicate, are Muscadel, Malvoisia, Pampot Roda, and Montona. The oxen are small and feeble; the sheep large, with beautiful and heavy fleeces. The pigs are large and fat; game is very plentiful, and consists of hares, rabbits, snipes, partridges, quails, &c. Poultry is very common. Their cheese is made of goats' and sheep's milk, and some of it is very good. Their exports, consisting of oils, wines, brandy, oranges and lemons, almonds, cheeses, capers and beans, amount in value to about 508,732*l.* 1*s.* 4*d.* This sum is augmented by the produce of some articles of manufacture. The inhabitants receive, in return, corn, salt provisions, sugar, coffee, rice, different sorts of snuff, cloth, silk stuffs, linens of different qualities, hosiery, hardware, medical drugs, planks and building wood, powder and shot for sporting, &c. all which may amount to the value of 124,833*l.* 6*s.* 8*d.* sterling. Hence it appears, that the balance in their favour amounts annually to about 383,899*l.* 11*s.* 8*d.* sterling.

The island of Majorca is not only destitute of navigable rivers, but its highways are inconvenient for travelling, and very much out of repair; so that all the articles of land carriage, from the interior to the sea, are conveyed on the backs of mules, or by carts of very clumsy construction. It has been said, that mines of gold and silver and precious stones were formerly found in this island; but of this there now remains no evidence. Its quarries of various sorts of marble and of stone are, however, numerous. In the marshes of Campos a quantity of natural salt is discovered, but for want of being worked it turns to little account: near the same town is a spring of sulphureous water, called the holy, or St. John's fountain, which is reckoned salutary in various complaints. In this island are some birds of prey, particularly the hawk; but venomous animals are very little known. The coral fishery is carried on in the bay of Alcudia during the months of July and August.

The manners of the Majorcans are the same with those of the Spaniards, and most strikingly resemble the Catalonians; they are both excellent soldiers and sailors. The dress of the peasants is a cap, which covers their short hair, a jacket down to the waist, large breeches, and shoes tied with a string; above the breeches they have a sort of frock. The neat and simple head dress of the females is called "rebozillo;" it consists of a double handkerchief, the upper part of which covers the head, and is hid under the chin, leaving only the face exposed, then extending over the shoulders, and falling down half of the back, the two ends meet, cross, and are tied before. Among the wealthy the rebozillo is an expensive article of dress, on account of the embroidery and lace. The women are in general fond of ornaments; those of fortune having a gold chain hanging along the petticoat, and sometimes a chain of the same metal from the corset, to which is fixed a valuable medalion: they have also all their fingers covered with rings, and make use of watches, bracelets, and other trinkets. When they go abroad, they wear a mantle like those in Spain, and carry in their hands a fan and a long chaplet, ornamented with gold beads, and a cross of the same metal.

The Majorcans value themselves on their fidelity to their sovereign; they are devout without bigotry, and their manners are soft and prepossessing. The women have a great degree of natural elegance.

Persons

Persons of distinction, men of business, and merchants speak Castilian, but the language spoken among the rest of the islanders is a kind of mixed jargon, the origin of which it would not be easy to trace. The authors, who have written on the Balearic islands, say, that the Limousine tongue is used, but this language is merely a dialect differently pronounced, and spoken in the southern provinces of France. The Balearic consists of Greek, Latin, Arabic, Catalonian, Languedocian, and Castilian, intermixed with Syriac, Carthaginian, and Vandal or Gothic words, or rather it is a strange medley of all. De Laborde's View of Spain, vol. iii. See *BALEARES Insule*.

MAJORCA. See PALMA.

MAJOR-DOMO, an Italian term, frequently used to signify a steward or master of the household.

The title of major-domo was formerly given in the courts of princes to three different kinds of officers. 1. To him who took care of what related to the prince's table, or eating; otherwise called *eleater*, *praefectus mensae*, *architriclinus*, *dapifer*, and *princeps coquorum*. 2. Major-domo was also applied to the steward of the household. 3. The title of major-domo was also given to the chief minister, or him to whom the prince deputed the administration of his affairs foreign and domestic, relating to war as well as peace. Instances of major-domos in the two first senses are frequent in the English, French, and Norman affairs.

MAJORIANUS, JULIUS VALERIUS, in *Biography*, an emperor of the western Roman empire, was raised to the throne in the year 457, having served with much reputation in the army. His address to the senate on this occasion spoke the language of one fully sensible of the duties incumbent on him. He appears to have possessed many excellent qualities both of the heart and head. The laws which he caused to be enacted, and which are extant at the end of the Theodosian code, are proofs of his attention to the happiness of his subjects, and the welfare of the empire. He granted a discharge to the inhabitants of the provinces from all arrears of tribute, and removed many exactions in the collections of the taxes. He enjoined severe penalties against the dilapidation of the public edifices of Rome, and made many wholesome regulations to encourage marriage, and restrain adultery. He rendered himself illustrious by his victories over the Vandals and Moors, who invaded his territories. He was at length the victim to the ambition of some of his chiefs, and compelled to abdicate his throne and authority in the year 461, after a reign of little more than three years; and in a few days after he was massacred by Ricimer, one of his generals. His character was that of an active, virtuous, and humane emperor. Univer. Hist. Gibbon.

MAIRAN, JOHN JAMES D'ORTOIS DE, an eminent French philosopher, who flourished in the eighteenth century, was born at Beziers in the year 1678. He devoted himself from a very early period to the study of literature and science, and obtained seats in the Academy of Sciences, and the French Academy. To the former he was chosen perpetual secretary, after the death of Fontenelle in 1741. While he continued in that office, he was punctual and diligent in performing its duties, and possessed the happy art of placing the most abstruse subjects in a clear and intelligible light. In his eulogies he nearly equalled his predecessor in the faculty of characterizing the subjects of them, and of impartially appreciating their merits. He died in 1771: he was author of a great number of publications on interesting topics, of which the following may be mentioned, "A Dissertation on Ice;" "A Dissertation on the Cause of Light of phosphoric Bodies and Glow-

worms;" "An historical and physical Treatise on the Aurora Borealis;" "A Letter to Father Parenin, containing several Questions relating to China," which is said to be a very curious work, and full of that philosophical spirit which characterizes the other works of the same author: some "Memoirs" published among those of the Academy of Sciences: "Dissertations," and "Eulogies" on deceased academicians, were printed in 1747.

For further information relative to Mairan, see Mem. de l'Acad. des Sciences, in which there are many curious articles concerning Harmonics and the philosophy of Euclid. He accounts for the medicinal powers of music in the following manner. "It is from the mechanical and involuntary connection between the organ of hearing, and the consonances excited in the outward air, joined to the rapid communication of the vibrations of this organ to the whole nervous system, that we owe the cure of spasmodic disorders; and of fevers attended with a delirium and convulsions, of which our Memoirs furnish many examples."

MAIRE, JOHN LE, a French poet, was born at Hainault in 1473, and died in 1524. He wrote among other pieces an allegorical poem, called the "Tales of Cupids, and of Atropos."

MAIRE, JAMES LE, a Dutch navigator, who sailed from the Texel in 1615 with two ships, and in the following year he discovered the straits, which bear his name in South America. After visiting New Guinea, he sailed to Batavia, where he was made prisoner, and his vessel confiscated, under the pretence of his having infringed on the rights of the Dutch East India company. He died on his passage to Europe in 1617.

MAIRE, LE, a French musician of the 17th century, is generally allowed the honour of having invented, or at least brought into use, in France, the syllable *si*, to express the 7th of the key of C, instead of repeating the *mi* in solmisation, by which students in singing escape the perplexing difficulty of the mutations. The title to the invention, small as it seems, has been often disputed; but having taken great pains to trace the first use of this syllable in singing, we have never been able to discover any musician to whom it is so justly due as Le Maire. With respect to the utility of this invention, we think it would be much extended if the sharp 7th of every major key, as well as that of *ut*, were called *si*.

MAIRE, LE, *Streight of*, in *Geography*, a narrow passage from the Atlantic to the Pacific ocean, between Terra del Fuego on the west, and the westward of Staten Land on the east, about five leagues long and as many broad; so called from Le Maire, who, with his companion Schouten, sailed from the Texel on the 14th of June 1615, discovered this passage: and they were the first who ever entered the Pacific ocean by the way of Cape Horn. In the account of lord Anson's voyage it is said, that it is difficult to determine exactly where this streight lies, though the appearance of Terra del Fuego be well known, without knowing also the appearance of Staten Land; and that some navigators have been deceived by three hills on Staten Land, which have been mistaken for the Three Brothers in Terra del Fuego, and so overshot the streight. But no ship, says lieutenant Cook, who passed this streight in January 1769, can possibly miss it that coasts Terra del Fuego within sight of land; for it will then, of itself, be sufficiently conspicuous: and Staten Land, which forms the east side, will be still more manifestly distinguished, for there is no land in Terra del Fuego like it. The streight of Le Maire can be missed only by standing too far to the eastward, without keeping the land of Terra del Fuego

Fuego in sight: if this is done, it may be missed, however accurately the appearance of the coast of Staten Land may have been exhibited; and if this is not done, it cannot be missed, though the appearance of that coast be not known. The entrance of the strait should not be attempted but with a fair wind and moderate weather, and upon the very beginning of the tide of flood, which happens here, at the full and change of the moon, about one or two o'clock: it is also best to keep as near to the Terra del Fuego shore as the winds will admit. By attending to these particulars, a ship may be got quite through the strait in one tide; or, at least, to the southward of Success bay, into which it will be more prudent to put, if the wind should be southerly, than to attempt the weathering of Staten Land with a lee-wind and a current, which may endanger her being driven on that island. The bay of Good Success lies about the middle of the strait, on the Terra del Fuego side, and is discovered immediately upon entering the strait from the northward; and the fourth head of it may be distinguished by a mark on the land, that has the appearance of a broad road leading up from the sea into the country: at the entrance it is half a league wide, and runs in westward about two miles and a half. There is good anchorage in every part of it, in from ten to seven fathom, clear ground; and it affords plenty of exceeding good wood and water. The tides flow in the bay, at the full and change of the moon, about four or five o'clock, and rise about five or six feet perpendicular. But the flood was two or three hours longer in the strait than in the bay; and the ebb, or northerly current, was with nearly double the strength of the flood. On the W. side of the Cape of Good Success, which forms the S.W. entrance of the strait, lies Valentine's bay, from which the land trends away to the W.S.W. for twenty or thirty leagues: it appears to be high and mountainous, and forms several bays and inlets. At the distance of fourteen leagues from the bay of Good Success, in the direction of S.W. $\frac{1}{2}$ W. and between two and three leagues from the shore, lies New Island; about two leagues in length from N.E. to S.W., and terminates to the N.E. in a remarkable hillock. At the distance of seven leagues from New Island, in the direction of S.W. lies the isle Evoutis, and a little to the W. of the S. of this island lie Barnevelt's two small flat islands close to each other; they are partly surrounded with rocks, which rise to different heights above the water, and lie twenty-four leagues from the strait of Le Maire: at the distance of three leagues from Barnevelt's islands, in the direction of S.W. by S. lies the S.E. point of Hermit's islands, which from most points of view may be taken for one island, or a part of the main. From the S.E. point of Hermit's islands to Cape Horn, the course is S.W. by S. distance three leagues. Cook observes, that between strait Le Maire and Cape Horn, they found a current setting, generally very strong, to the N.E. when they were in with the shore; but they lost it when they were at the distance of fifteen or twenty leagues.

Though the doubling of Cape Horn, says Cook, is so much dreaded, that in the general opinion it is more eligible to pass through the strait of Magellan, we were not once brought under our close reefed top-sails after we left the strait of Le Maire. But supposing it more eligible to go round the Cape than through the strait of Magellan, it may still be questioned, whether it is better to go through the strait of Le Maire, or stand to the eastward, and go round Staten Land. In the account of lord Anson's voyage the advice is, that all ships bound to the South seas, instead of passing through the strait of Le Maire, should constantly pass to the eastward of Staten Land, and should

be invariably bent on running to the southward as far as the latitude of 61 or 62 degrees, before they endeavour to stand to the westward. "But, in my opinion," says captain Cook, "different circumstances may at one time render it eligible to pass through the strait, and to keep to the eastward of Staten Land at another. If the land is fallen in with to the westward of the strait, and the wind is favourable for going through, I think it would be very judicious to lose time by going round Staten Land, and I am confident, that by attending to the directions I have given, the strait may be passed with the utmost safety and convenience; but if, on the contrary, the land is fallen in with to the eastward of the strait, and the wind should prove tempestuous or unfavourable, I think it would be best to go round Staten Land. But I cannot, in any case, concur in recommending the running into the latitude of 61 or 62°, before any endeavour is made to stand to the westward. We found neither the current nor the streams which the running so far to the southward is supposed necessary to avoid; and, indeed, as the winds almost constantly blow from that quarter, it is scarcely possible to pursue the advice. The navigator has no choice, but to stand to the southward, close upon a wind, and by keeping upon that tack, he will not only make southing, but veering; and, if the wind varies towards the north of the coast, his veering will be considerable. It will, indeed, be highly proper to make sure of a veering sufficient to double all the lands, before an attempt is made to stand to the northward, and to this every man's own prudence will, of necessity, direct him." Hawke's Voyages, vol. ii.

MAIRE, a small island in the Mediterranean, near the coast of France. N. lat. 43° 14'. E. long. 6° 24'.

MAISBINNI, a town of Abyssinia; six miles W. of Axum.

MAISERRY, a town of Bengal; 10 miles S. of Ghidore.

MAISEY, a town of Hindoostan, in Bahar; 45 miles N. of Patna. N. lat. 26° 22'. E. long. 85° 18'.

MAISNAH, a town of Bengal; seven miles N.N.W. of Goragot.

MAISTRE, ANTONY DE, in *Biography*, a French writer, was born at Paris in 1608; he was brought up to the bar, but quitted the profession, and entered into the society of Port Royal, where he died in 1658. The greater part of his life he spent in acts of the severest mortification, in writing various works, and in the study of theological subjects. His principal pieces are "Pleadings," which have been repeatedly reprinted; a French translation of the treatise "On the Priesthood by St. John Chrysostom;" a translation of the works of St. Bernard: he had employed himself on a French version of the Old and New Testament. Moreri.

MAISTRE, LOUIS ISAAC LE, better known by the name of *Sacy*, brother of the preceding, was born at Paris in the year 1613. He was brought up for the church, and was ordained priest in 1648. The persecution of the Jansenists, in which the members of Port Royal were involved, obliged him to conceal himself in the year 1661, but being discovered in the place of his retreat in 1666, he was sent to the Bastille. Here he was confined more than two years and a half, during which time he employed himself on the translation of the Bible, and finished the whole of the Old Testament. After his liberation he completed his version of the New Testament, which he went over thrice, before he could pronounce it finished. His works are extremely numerous, and the topics very various. He was a perfect

master of the French language, and wrote it elegantly. Moréri.

MAITEA, in *Geography*. See OSNABURG *Island*.

MAITED, a town of Persia, in the province of Ker-man; 16 miles N.E. of Sergian.

MAITLAND, JOHN, in *Biography*, lord Thylstane, and chancellor of Scotland, was born in 1545. He accompanied king James VI. to Norway, where his consort, the princess of Denmark, was detained by contrary winds. He died in 1595. He was author of "Epigrammata Latina," published in the "Deliciae Poetarum Scotorum." Gen. Biog. Dict.

MAITLAND, WILLIAM, a topographical and antiquarian writer, was born at Brechin, in Scotland, in 1693. His business as a hair merchant led him to travel, and he visited Sweden, Denmark, and Germany, and finally settled in London. Here he began to apply himself to the study of antiquities; and in 1739 published the first fruit of his labours, which was his "History of London." The work, which was an improvement upon that of Stowe, became popular, and has since been several times reprinted, with considerable additions: it has likewise furnished materials for many smaller and more modern publications. Soon after the publication of this work, the author is supposed to have retired to his native country, for the purpose of pursuing enquiries into its historical antiquities, and, in 1753, he published "A History of Edinburgh." Success in this instance led him to extend his researches to a much wider compass, and he employed himself in writing "The History and Antiquities of Scotland, from the earliest Account of Time to the Death of James; continued by another Hand to the Accession of James VI. to the Crown of England." This work was published in two volumes folio in 1757; the same year the author died at Montrose. Mr. Maitland deserves great applause for his industry, but he was not reckoned competent for such a task, either with regard to learning or critical acumen.

MAITLAND, HENRY, a surgeon, is worthy of notice, principally as being the first person who performed the operation of *inoculating* the small-pox in England. Mr. Maitland resided at Constantinople, in the early part of the 18th century, with the Hon. Wortley Montague, then ambassador at the Ottoman court, where the only son of that gentleman was inoculated, at the age of six years, in 1717: and, on their return to England, Mr. Maitland inoculated the infant daughter of the same gentleman, in April, 1721. He published a detail of these cases, and of those of some condemned criminals in Newgate, in February, 1722, in a pamphlet, entitled "An Account of Inoculating the Small-Pox;" and subsequently, a second pamphlet in "Vindication" of the former, in reply to the attack of Dr. Wagstaffe. See INOCULATION.

MAITRE à CHANTER, *Fr.*, a singing-master. Rousseau has so well pointed out the functions of a singing-master in teaching the elements of the vocal art, that we shall translate the chief part of his article on the subject. He includes the master's task in two principal objects. The first regards the cultivating and forming the voice, by making it capable of all that belongs to singing, with respect to compass, truth of intonation, clearness and sweetness of tone, execution, swelling and diminishing the notes, hitting distances with precision, and acquiring a free and open shake.

The second object regards the study of the musical characters; that is, acquiring a facility in reading music at sight, as accurately and readily as a printed book, in the student's own language.

VOL. XXII.

A third part of a master's business is to enforce the duty of pronouncing and articulating the words with accuracy and energy; because defects in pronunciation are much more sensible in singing than speaking; as the finger is expected to tune and soften the harsh syllables, and render the soft still more sweet.

Millieu used to say, that a voice should be so cultivated and exercised in *solfeggi*, as to resemble a ball of wax, so long tempered in the hand that it can receive any impression.

Rousseau says nothing of *expression*, but that must come from the heart as well as the voice. It is perhaps only to be learned by imitation, and taught by example. There are many clear and powerful voices which give the hearer no pleasure, however accurately they may execute the notes; while a feeble voice has often the undefinable power of affecting us by a natural pathos and interesting expression that touches and delights us the instant it is heard. See CANTARE, SOLFEGGIA, and EXPRESSION.

MAITRE-JEAN, ANTHONY, in *Biography*, an oculist and surgeon, was educated at Paris, and practised at Mery on the Seine, with great reputation, at the beginning of the eighteenth century. He was particularly distinguished for his success in the treatment of diseases of the eyes, both the healthy and morbid structure of which he had investigated with great industry and accuracy, as his work, entitled "Traité des Maladies de l'Œil, et des Remèdes propres pour leur Guérison," 1707, sufficiently proves. This treatise, which was several times reprinted and translated, was long a standard, and is still entitled to esteem. It contained the first satisfactory proofs that the seat of cataract was exclusively in the crystalline lens, and treated copiously on all the varieties of the operation of couching. He likewise published, "Observations sur la Formation du Poulet," Paris 1722, with figures, drawn by himself; a work which contains many original experiments and remarks, and which, according to Haller, is not sufficiently esteemed. Maitre-Jean was a corresponding member of the Academy of Sciences at Paris, and some of his papers were printed in the Memoirs of that learned body. Eloy Dict. Hist. de la Méd. Gen. Biog.

MAITS, in *Geography*, a lake of Prussia, in Natangen; 20 miles S. of Rastenburg.

MAITTAIRE, MICHAEL, in *Biography*, an eminent bibliographer and philologist, was born about the year 1668. The place of his birth has not been ascertained, but it has been inferred from the name that he was descended from parents, refugees from France. He was educated at Christchurch, Oxford, and took his degree of M.A. in 1696: previously to this, he had been nominated second master of Westminster-school, a post which he occupied till 1699. He was intended for the church, and wrote some controversial pieces, but it does not appear that he took orders. He was patronized by the first earl of Oxford, and enjoyed the favour of the second earl, and was afterwards appointed tutor to lord Chesterfield's natural son, Mr. Stanhope. He was deeply skilled in classical learning, and was author of many works, which still bear a good reputation. His first piece was entitled "Græcæ Linguae Dialecti;" which was succeeded by an "English Grammar." Typographical antiquities were his study and delight, and he gave the public, in connection with these subjects, the following works: "Stephanorum Historia, vitas ipsorum ac libros complectens;" "Historia Typographorum aliquot Parisiensium;" "Annales Typographici ab artis Inventione." In the first volume, the history of printing was brought down to the year 1500: the second continued it till

1536; and the third to the year 1664. This was published in 1725. A volume, published at Amsterdam in 1773, usually reckoned the fourth, is, in fact, a revision of the other three. This is a work of great labour, and highly regarded by bibliographers. A supplement to it was published in 1789, at Vienna, since which an enlarged edition of the whole has been printed at Nuremberg. Mr. Maittaire edited a number of classical authors, both separately and in a collected form: of these may be mentioned "Opera et Fragmenta veterum Poetarum," in two volumes, folio: "A Greek Testament;" "Miscellanea Græcorum aliquot Scriptorum-Carmina;" "Anacreontis Carmina;" and an edition of Livy in seven volumes 12mo. He addressed to the empress of Russia, a "Carmen Epicum," of his own composition; and published a volume of Latin poems under the title of "Senilia."

MAJUMA, or NEW GAZA, in *Geography*, a sea-port town of Palestine, near Gaza; which see.

MAIXENT, ST., a town of France, in the department of the Two Seves, and chief place of a canton, in the district of Niort; 6 miles N.E. of Niort. The place contains 5000, and the two cantons 19,767 inhabitants, on a territory of 230 kilometres, in 14 communes.—Also, a town of France, in the department of the Sarthe, seated on the Seure; badly built, surrounded with walls, and containing an ancient castle with two fauxbourgs, and about 5000 inhabitants; 6 miles S. of La Ferte Bernard.

MAIZ, in *Agriculture*, a provincial term applied to a large light sort of hay basket, in some districts.

MAIZE, or INDIAN CORN, in *Botany*. See ZEA.

MAIZE, in *Agriculture*, a species of grain much used for food in America, under the name of Indian corn. It is very productive; the size of its ears, where it is cultivated on good warm soils, being, on a medium, nearly a span long, having commonly eight or more rows of grain, each of which usually contains about thirty seeds of various colours, as red, white, yellow, blue, olive, greenish, blackish, speckled, striped, &c. sometimes in the same field and same ear; but the white and yellow are the most common: nor does this diversity of colours ever reach beyond the outside of the grain, the flower of which is always white, with a little tinge of yellow. The seeds, which are as big as large peas, are round at the outer surface, very smooth, and set extremely close in straight lines. The ear is clothed and armed with several strong thick husks, which defend it not only from unseasonable rains, and the cold of the night (for it does not ripen fully in some places till towards the latter end of September), but also from birds. In the northern districts, the stalk of this plant, which contains a remarkable sweet pith, and is jointed like the sugar-cane, does not grow near so high as in the southern parts. It has long leaves, almost like the flag at every joint, and at the top a bunch of flowers of various colours. Its culture upon any extensive scale has not hitherto been attempted in this climate.

Soil, Preparation, and Method of sowing or planting.—This kind of crop may be grown on most sorts of soils. On a light, poor, sandy soil, in Miller's trials, the method of preparation for it was to have the land ploughed up deep before winter, and laid up in high ridges till the spring, when it was broken fine with the harrow. It was ploughed again in April, laid level, harrowed smooth, and then sowed in drills, four feet asunder, into which the seeds were dropped at the distance of about eight or nine inches from each other. When the plants were about three inches high, they were thinned with a hand-hoe, by cutting up some of them where they grew too close, and the intervals between the rows ploughed shallow, to destroy the young weeds: but when the stems

were advanced, the ground in the intervals was ploughed deep, and the earth laid up to the plants on both sides; and when the weeds began to grow again, a third ploughing was given, to destroy them. This kept the ground pretty clean from weeds till the corn was ripe, as the season did not prove wet; otherwise a fourth ploughing would have been necessary.

In Ireland, in the experiments of sir Richard Bulkeley, the grains were set a foot asunder, in rows about a yard distant from each other. In the former of these cases, there were from each stalk from three to six spikes of grain, and in the latter from three to six stems, and upon each stem three spikes, or ears of corn, with two hundred and forty grains on each spike, which was an amazing increase.

In M: Duhamel's attempts to raise this sort of grain, he found it to thrive better in a light and sandy soil, than in stiff and clayey land. It did not answer without dung; and the ground intended for it received two good ploughings in March. A third ploughing, given towards the end of April, made the furrows for the seed; and what clods remained after this were either broken by hand or the roller.

And a fine clear day was chosen in May for sowing the seed, which was done by making at the bottom of the furrows, with a stick or other instrument, small holes, into each of which two grains of maize were dropped. The furrows were a foot and a half asunder, and the holes at the same distance, disposed in such a manner, as to form a kind of quincunx. When the corn-plants appeared, the weakest of the two were plucked up, where both seeds had sprung; and where neither of them had grown, two new grains were planted. Towards the middle of June the ground was hand-hoed round each plant; and as they *stud* at the bottom of the furrow, the mould which crumbles down from time to time, laid fresh earth to their roots, and helped to support them. About the end of July, a slight hoeing was again given them, which was the last; and the earth laid towards the roots of the plants.

It is suggested, that the panicles of the male flowers, which grow at the top of each plant, and are well known not to contain any grain, should be cut off about the middle of August, but care must be taken that the grain be impregnated before this is done, which may be known by the turgid appearance of the outward covering of the ears: and they should not be cut off from all the plants at the same time, as some of the ears are not impregnated till a fortnight after others. These panicles are excellent food for cattle. When they are cut, or shortly after, all the leaves should be stripped off the stalks, together with all the blighted and smutty ears: for it is said, that the good ears would not grow so large, nor the grains be so well nourished, if they should be left upon the stalks. All these leaves and ears are given as fodder to oxen.

The proper time for reaping maize is towards the end of September. The ears are then gathered by hand, and put into baskets, in which they are carried, and laid in heaps, from space to space, in the field, after which they are loaded in carts, carried home, and spread upon an even floor prepared for that purpose. They are then taken out of their sheath, or hood, and dried in the sun, before they are laid up in the granary, or else the grain is taken out at that time. Maize, which has been well dried in the sun, will keep several years, and not be the less fit for sowing. The granary should be very dry, and the corn laid up in it should be turned at least every three months, to prevent its growing musty, or being attacked by insects. There are two ways of taking out the grain; the first, which is the most expeditious, is by thresh-

M A I Z E.

ing it with a flail; but in this method a deal of the corn is broken or bruised. The 2d, and more common, is by rubbing the ears hard against the edge of a flat piece of iron; this easily separates the grains from the spike, or cob, without hurting them, and this remainder of the ear is very good food for oxen. As soon as the ears are gathered, the stalks remaining in the ground are plucked up, and laid by for winter fodder for oxen or other cattle. The field is afterwards ploughed up as soon as possible, it being the general opinion of farmers, that the roots of the maize would otherwise continue to suck up the rich particles of the earth: whether this be true or not, their notion is, that if this ploughing should be deferred, the next year's crop would certainly suffer by it.

When maize is planted only for fodder, particularly for cows and oxen, it is sowed very thick, and harrowed in, or covered with a rake, in a good soil which has been ploughed twice, and well dunged; but it is observed, that in these thick sowings, all the female flowers are barren, and produce no grain: and it likewise is so great an impoverisher of land, that though the ground be dunged every time it is planted, wheat never does so well where this corn has grown, as in the neighbouring fields where it never was grown.

In M. Amien's trials it was found of importance to sow maize rather in the beginning than at the latter end of May, because, if it be sown early, the plants will have acquired sufficient strength, before the great heats, to shoot out then with vigour, and the ears be not liable to that barrenness to which they are subject when sown late; besides, the stalks will be stronger, and their ears larger and fuller of grain; the ears of maize also are greatly hurt by cutting the panicles too late, which ought to be done before the hoods are open. By leaving a plant with its male flowers at every twenty feet distance, all the female ears may be impregnated.

In order to ascertain whether it is best to sow maize thick or thin, he planted three different spots of ground with this corn in April; the seed used for the first, where the grains were placed about a foot and a half asunder, according to the common practice of the country, weighed one ounce and one penny-weight; the second, in which the grains were only a foot asunder, was sowed with two ounces and two penny-weights of seed; and the third, in which they were but six inches apart, was sowed with four ounces and a half. The first of these spots produced eighteen pounds and four ounces of grain; the second fifteen pounds seven ounces; and the third eleven pounds two ounces. A manifest proof, M. Amien thinks, that some sorts of grain do not thrive unless they are sown very thin, and that for want of this precaution, a great deal of corn is often lost, and the crops considerably diminished.

It is found that this plant, when cut green, affords a good cattle food: the grain is likewise highly useful for feeding poultry and hogs, and, when ground into flour, for various purposes.

But in America, according to a late writer, the common method to prepare land for Indian corn, is in the fall (Autumn) to plough it, or what is termed *flusbing* it. The soil is raised in a rough manner by ploughing broad furrows; it being so thin, that it is not turned over, but stands very much on the edge: the ploughs are of a bad construction. In the latter end of April, or beginning of May, the plan is to *lift* it out, that is, crossing the field five or six feet asunder, setting two furrows back to back, then the like the other way, which forms a sort of hill where these furrows cross each other. The practice is then to go with a large hoe, such as that its weight will break the clods in the same manner as malls (beetles) for that use, and make the mould

very fine, something in the manner that gardeners do for cucumbers in the field-gardens in this country. In these hills are put four or five corns, and this is generally done in the first of May.

Reckoning four corns to one hill, four thousand only will be required to plant an acre containing a thousand hills. When the corn is come up, the custom is to go with their hoes, and draw a little mould to the plants, destroy any weeds that may appear, and plant fresh corn, if any be wanting, which often happens; that done, to plough from those hills both ways, then to go with the hoes, and work the hills again, and to draw the plants of an inferior kind out, leaving two of the best on each hill, or if the land be good, three and sometimes four, and to transplant those drawn out where any are wanting. However, when more than two plants are left on one hill, there will be little corn, but much tops and blades. Then to plough all the land towards the plants one way; after this it is necessary to what they term *sucker* them, that is, to take off any young sprouts that have tillered, otherwise the corn will not grow in the ear to its proper length or size, but grow short, what they call *cobbings*; this done, just before it goes into filk, they plough the land to the corn the contrary way, which is five times in all. The expence would be about seven pounds *per acre*, if the work were done by hired labourers, and horses for ploughing.

Expences per Acre.

After the last time of ploughing, which is during the latter end of August, some of them sow wheat under furrow, for which the Indian corn crop is a preparation, but which is harrowed in by others in September; the ploughing is done in a scimming manner, very thin.

It is found that "the raising of Indian corn is an absolute preparation for wheat, rye, or winter barley, and perhaps better for the land in that hot country, than if nothing was grown, costing little more than the seed wheat. It is a general practice to cut the tops, and pull the blades, before they sow the wheat; the topping and blading is done by cutting the tops off with a knife, just above the uppermost ear, as there are or ought to be two ears on each stalk, which are thrown out about four feet above the ground; the writer has had from five to seven ears put out filk, but they never came to perfection."

The writer, however, in his own practice, put the corn into the ground in drills, at different distances from three to

six feet, harrowing the seed in, and found on actual trials, that a better crop of Indian corn may be raised by planting at six feet apart, and eighteen inches in the drills, than by any other mode which he has attempted, where the land is rich. Upon very poor land he does not, however, doubt but that the hill method may be superior, as by hoeing and ploughing there may be rather more of the best earth added to the roots of the corn. This sort of drilling was found the best and cleanest method, as well as probably the cheapest.

It is further stated, that "good Indian corn will be from twelve to fourteen feet high, and that the white corn is much higher than the yellow; but the yellow is by far the sweetest, although the tops and blades are not so abundant. There are several kinds or varieties, both of yellow and white corn; the yellow is earlier than the white by one month." And, that, "the tops are set up in bunches or shocks; the blades are pulled off, tied up in small bundles, about one pound each, and hung on one of the corn stalks by the tie or band, and in two or three days it is ready to carry." It is added, that "the usual method of preserving them for the winter is to make what is termed a fodder-house, by setting up long grained posts, and laying a rail upon the top, then placing other rails upon the ground, leaning against what may be

termed the ridge-tree, they then lay the tops on like thatch, the blades are stored within the house; the husks are put into the house after the corn is gathered and husked, and given in the winter to the cattle. The white corn generally hangs on till frosty weather, as it takes a great deal of curing or hardening, having a very thick husk and a large cob. One leaf hangs over another, and the ear hangs downwards, and would not take harm all the winter, were not the ear to drop off the stalk. It is generally gathered in frosty weather, and sometimes when snow is on the ground. One reason for this may be, that it does less injury to the wheat, as they are obliged to cart upon the land where the wheat grows. The corn is taken from the cob by hand, as it cannot be threshed as grain is. The farmers have generally a husking feast, when all the neighbours come and help to husk."

It may be noticed that this sort of crop was formerly introduced in rotation with other sorts of grains, so as to greatly injure the ground, as well as be less productive; and the practice still prevails in many places; but in the more improved methods of cultivation, and where the better sorts of husbandry prevail, it is now the custom to grow this kind of grain in courses with crops of the green ameliorating sort, such as these below, and in that manner.

Courses of Crops.

I. Old American Maize Course.

1. Maize,
2. Wheat or rye,
3. Lay, or mean pasture;
- or,
1. Maize,
2. Naked fallow,
3. Wheat,
4. Lay, or mean pasture.

II. Better Maize Course.

1. Maize,
2. Wheat, or spring barley,
3. Clover,
4. Rye or winter barley,
5. Clover,
6. Clover.

III. Improved Maize Course.

1. Maize,
2. Beans,
3. Barley,
4. Clover,
5. Wheat,
6. Clover.

This is not a beneficial crop, and from calculation it cannot; yet it must be a useful one, as it is the whole support of the American population. They begin to eat it as soon as it is formed in what is termed roasting ears; they boil them, and eat the corn in the same manner as we do green peas, with drawn butter, and no bacon, ham, beef, mutton, or any other kind of meat. The blades and tops feed the horses, cattle, and sheep; the corn feeds both man and beast, and is very excellent food for fowls, hogs, &c. The people eat it in *hominy*, mush and bread, or cakes; the *hominy* is made in like manner to our creed wheat buttered, by knocking the husk off in a wooden mortar; the mush is made of the flour as our halty pudding, and eaten with milk or treacle. The better sort of people make a very nice cake, with eggs and milk, about the thickness of pyfflects, or what are called crumpets in London; the lower class of people mix the flour with water, make a sort of paste, and lay it before the fire on a board or shingle to bake, and generally eat it hot, as it is but very indifferent food when cold; it is called *Johnny cake*.

MAIZIERES, in *Geography*, a town of France, in the department of the Upper Marne, and chief place of a canton, in the district of Joinville; four miles N.W. of Joinville.

MAKADAMA, in *Mythology*, a name of the Hindoo god of love, *Kama*; which see.

MAKALLA, in *Geography*, a sea-port town of Arabia, in the province of Hadramaut; 60 miles S.S.W. of Hadramaut.

MAKANNA, a kingdom of Africa, situated between the rivers Senegal and Gambia; 300 miles from the Atlantic ocean.

MAKARA, a fabulous marine monster, frequently mentioned and alluded to by Indian authors. It is borne in the banner of *Kama*, the Hindoo god of love, as noticed under that article; one of whose names is hence Makara-ketu. It is also the sign Capricorn in the Indian zodiacs, and some writers deem it the horned shark. A combination of the goat and fish in that sign is not unfrequently seen on the zodiac of several nations, both eastern and western, of which notice is taken under the article CAPRICORN.

MAKAREV, in *Geography*, a town of Russia, in the government of Niznei-Novgorod, on the Volga; 24 miles E.N.E. of Niznei-Novgorod. N. lat. 56° 25'. E. long. 44° 44'.—Also, a town of Russia, in the government of Koltrom, on the Unza; 80 miles E. of Koltroma. N. lat. 58° 50'. E. long. 44° 14'.

MAKAYA, a town of Africa, in the kingdom of Kayor, about 21 miles from the Atlantic ocean. N. lat. 15° 20'. W. long. 16° 24'.

MAKE, in *Law*, signifies to perform and execute.

Thus, to make his law, is to perform that law to which a man had formerly bound himself; *v. gr.* to clear himself of action commenced against him by his own oath, and the oath of his neighbours, otherwise called to wage law. See *WAGER of Law*.

So, to make services or customs, is nothing else but to perform what belongs to them.

MAKE-hawk, in *Falconry*. See **HAWK**.

MAKE, To, in *Sea Language*, is variously applied: *e. g.* to make a board. See **BOARD**.

To make the land, is to discover it from a distant situation, in consequence of approaching it after a sea voyage: to make fail is to increase the quantity of sail already extended, either by letting out the reefs, and by hoisting an additional number of small sails, or by either of these operations separately: to make stern way, is to retreat or move with the stern foremost: to make water casually signifies to leak; but a ship is said to make foul water, when running in shallow water, her keel disturbs the mud or ooze, lying at its bottom.

MAKEN KUR-ASSAY, in *Geography*, one of the Kurile islands, about 20 versts in length, and ten in breadth. It is scattered with rocks, especially about the shores, and many meadow grounds and moist places. It has no standing wood, but a few shrubs; its red foxes are few; sea-beavers and seals lie about its shores. It has neither lake nor stream, though it abounds with springs; it is altogether uninhabited.

MAKEFIELD, *UPPER and Lower*, townships of America, in Berks' county, Pennsylvania, the former containing 1101, and the latter 963 inhabitants.

MAKENABAD, a town of Persia, in Segestan; 90 miles S.E. of Zareng.

MAKER, a village of England, in the county of Devon, on the Cornish side of the Tamar, near Plymouth sound: the church tower of which is a sea mark. N. lat. 50° 20'. W. long. 4° 11'.

MAKER-DUR, a town of Hindoostan, in the circar of Kitchwara; 22 miles N. of Budawar.

MAKERRA, a river of Algiers, that rises about 26 miles E. from Tremecen, and after a course of about 30 miles changes its name to Sig.

MAKESIN, a town of Asiatic Turkey, in the province of Diarbekir, on the Khabur; 105 miles S.W. of Mosul.

MAKIAN. See **MACKIAN**.

MAKINBOY, a name given by the people of Ireland to a kind of spurge, or tithymale, common there: this is a very violent purge, as all the other spurges are; but the Irish have an opinion that it will produce this effect only by being carried in the pocket. This opinion, which had been universally believed for many ages, was proved to be false by Dr. Mullen, who carried a large quantity of it about him many days together, on purpose to give a fair trial; but it had not any the least effect on him.

MAKING-UP, a term used by distillers to express the bringing spirits to a certain standard of strength by the addition of water. See **LOWERING**.

It is used principally in the distilling spirits, after their first drawing, either by way of rectifying them, or of giving them the virtues of aromatic ingredients, in order to make the compound waters; such as cinnamon, aniseed, and the like. See **DISTILLATION**.

In the making of these compounds, some use an alcohol, or totally inflammable spirit, which is much the best method; others use ordinary proof spirit of malt, or molasses. If the latter be used, it is best not to put any water with it into the still; but if the former, so much water is to be added as will reduce it to the proof strength, which is just an equal quantity. When this is done, there should be drawn off three-fifths of the whole by distillation; and the far better way would be to keep this liquor in this very state, which is just the strength of the *trois-cinques* brandy of the French: but as people require these waters to be kept for drinking, in such a state as not to exceed at the utmost the strength of

proof spirit, generally to fall much short of it, it is necessary to reduce this three-fifths to the whole, or more than the whole quantity of the proof spirit put into the still. The apothecaries, to this end, usually let the still continue to work without changing the receiver, till an equal quantity is produced to the spirit put in, or one-fourth more; it being the usual standard in these waters to have five quarts made from a gallon of the spirit. By the method of doing this, by letting the still run, the fumes are taken into the water, and give it a rapid and disagreeable taste. Instead of this, the distiller, when he has drawn off his three-fifths of the quantity of proof, makes up the whole of the destined quantity, by adding the two other fifths, or more than that, if required, of common water, in which it is also customary to dissolve some fine sugar, and this gives a fulness in the mouth to the water, and makes it mellow, or lose the fiery taste of the still much sooner. If it be only made up to the strength of proof, it will mellow much sooner than if reduced one-fifth below that standard, as the oil is much more perfectly dissolved in spirit of a standard proof strength, than in such as is weaker. The water employed in the making up, should be either soft and clear river-water, or else spring-water rendered soft by distillation, otherwise it is apt to turn the water thick, and precipitate a sediment, especially if the water be drawn lower than proof, or if the spirit, originally employed, partake of an alkaline nature from the salts used in its rectification, as is usually the case in the malt spirits, the gross oil of which requires to be separated by mixing salt of tartar or pot-ash with it in the still in the rectification.

When it is necessary to make up waters lower than proof, they are generally cloudy; but this may be remedied, and they may be fined down in a day or two with a small quantity of alum, or with whites of eggs, or the jelly of iisinglass beat up to a froth, and mixed in the same manner as is usually done in the refining of wines.

The sugar, added to these cordial waters, has not only the advantages of mellowing and filling the mouth, but it unites the oil to the spirit in a manner that it could never be united in without it. Shaw's Essay on Distillery.

MAKKEDAH, in *Ancient Geography*, a royal city of the tribe of Judah, in Palestine, near which the five kings of the Amorites were put to death by Joshua. It was once a very strong city, and placed by Eusebius about eight miles from Eleutheropolis.

MAKO, PAUL, in *Biography*, canon of the cathedral of Waizen, a learned Hungarian, descended from a noble family, was born at Jasz-apatin in the year 1724; he entered the order of the Jesuits, and made such progress in his studies, that he was soon appointed teacher of logic and metaphysics at Tymau, and afterwards professor in the university of Vienna. He filled the same department afterwards in the Theresianum, where he procured, by his amiable disposition, the love and esteem of all the young nobility who frequented that seminary from almost every part of Europe; and when the Hungarian high school of Tymau was afterwards transferred to Ofen, the empress, Mary Theresa, appointed him a member of the academic senate. He exerted himself with great zeal and ability to introduce a taste for scientific pursuits into Hungary; and during his moments of leisure, he pursued, with unabating ardour, the belles lettres. He died in 1793. The principal works which he left behind him are, "Descriptio Provincie Moxitarum in regno Peruano, quam e Scriptis posthumis Franc-Xav. Eder e Soc. Jet. Annis XV. sacri apud eisdem curionis digessit, enopolivit et adnotatiunculis illustravit, P. Mako;" "Dissertatio Phys. de natura et remediis Fulminum;" "Elementa Ma-

theseos puræ;" "Elementa Geometriæ Puræ." Gen. Biog.

MAKONDA, in *Geography*, a town of Africa, in Loango, on the sea-coast; 40 miles N.W. of Loango.

MAKOONDA, a town of Hindoostan, in the country of Allahabad; 60 miles S. of Allahabad. N. lat. $24^{\circ} 33'$. E. long. $84^{\circ} 37'$.

MAKOVITZE, a town of Hungary; 16 miles S.E. of Palotza.

MAKOUSKI, JOHN, in *Biography*, generally known by the name of *Maccovius*, a celebrated Polish Protestant divine, and professor of divinity at Franeker, was born at Lobzenic in the year 1588. He went through his course of philosophy at Dantzic, under the celebrated Keckerman, and rose to eminence among his fellow students. He was admitted doctor of divinity at Franeker in the year 1614, and was in the following year elected to the professorship of divinity in the university. In the exercise of the duties attached to his office, he was accused of heresy, and the charge being made, it was examined by the synod of Dort, who gave it as their opinion, that he was unjustly accused. He died in 1644, leaving behind him several works relating to the controversy against the Arminians and Socinians. Moreri.

MAKOVSKOI, in *Geography*, a town of Russia, in the government of Tobolsk, on the Ket; 48 miles W. of Eniseisk.

MAKOW, a town of Persian Armenia; 81 miles S. of Erivan.—Also, a town of the duchy of Warsaw; 40 miles N.N.E. of Warfaw.

MAKRAN. See MECRAN.

MAKRAN, a town of Arabia, in the province of Hedsjas, the residence of a scheid.

MAKSCHOUS, a town of Arabia, in the highlands of Hedsjas, the residence of an independent sovereign scheid, whose domain contains several towns and villages. This scheid is of the tribe of Harb, and he is so powerful that on occasion he can bring 2000 men into the field. During the months favourable for pasturage, the most distinguished persons of this tribe live in tents; during the residue of the year, they inhabit the towns and villages. The lower class live commonly through the whole year in huts thatched with grafs. Their principality is situated upon the mountains between Mecca and Medina. The chief of the tribe of Harb is the person who principally harasses the caravans, and lays them under contribution. Unless the Syrians and Egyptians pay the tribute he demands, for permission to pass through his territories, he musters up an army of his own subjects and his neighbours, all of whom are very willing to pillage a caravan.

MAKSENOVKA, an ostrog of Russia, in the government of Irkutsk, on the coast of the Frozen sea. N. lat. 72° . E. long. $134^{\circ} 24'$.

MAKSIMA, ST., a small island of Russia, in the Frozen sea. N. lat. $71^{\circ} 20'$. E. long. $133^{\circ} 34'$.

MAKSUDEGHI, a town of Persia, in Farfistan; eight miles S. of Komsha.

MAKSZYN, a town of Bulgaria; 50 miles W.S.W. of Ismael.

MAKTIN, a town of Bessarabia; 34 miles S.S.W. of Akerman.

MAKU, or ST. THADDEUS, a town of Persian Armenia, on the Akfai, a river which runs into the Aras; 60 miles S. of Erivan.

MAL DES ARDENS, or *Morbus ardentium*, in *Medicine*, terms which have been applied by some medical writers to two or three different epidemic diseases, in an acceptation

nearly synonymous with the *ignis Sti. Antonii*, and *ignis sacer* of others. See *IGNIS sacer*, and *ERGOT*.

MALA, or DEMALA, in *Geography*, a town of European Turkey, in the Morea; 45 miles S.E. of Argos.

MALA, a river of Peru, which runs into the Pacific ocean, S. lat. $12^{\circ} 40'$.

MALA Aurea, in *Botany*, a name by which some authors have called the *poma amoris*, or fruit of the lycopericon.

MALAAC, in *Geography*, a town of Meckley, 12 miles S.S.E. of Munnypour.

MALABAR, a name given to the western coast of Hindoostan, from cape Comorin to about 100 miles S. of Goa.

The name of Malabar is said to be derived from the Malabar word "Malayalam," denoting "mountainous;" the terminations *ar*, *tar*, and *bar*, signifying, in that language, a *people* or *nation*; consequently "Maleiwar" or "Maleibar" would denote as much as "mountaineers," or "inhabitants of the mountains." The syllable *lai*, when uttered with rapidity, takes the sound of *la*, and the name of Malabar was applied to the people, from the hilly country, who descended from the mountains, and settled upon the coast.

That tract of country which is properly called the Malabar, lies nearly in the direction of N.W. and S.E. from cape Comorin to Canara, between the 18th and 14th degrees of north latitude; to the east, it is divided from the coast of Coromandel, by a high range of mountains, called the "Ghauts," and to the south-west it is washed by the Arabian sea. The principal kingdoms which it comprehends are those of Travancore, Cochim, Cranganore, and Calicut; of which the first has become the principal and the most powerful. The Malabar, or rather the forts of Coylang, Cali Coylang, Cranganore, and Cananore, established by the Portuguese on that coast, were conquered by the Dutch in the years 1662 and 1663, and they long retained the possession of all, except Cananore. The extent of the Dutch company's possessions from Coylang to Chittua, Cananore not being under their dominion, comprised, from S.E. to N.W. a distance of 32 leagues; but if we except *Paponetty*, (which see,) and some small districts interspersed along the coast, the company possessed no other actual property in the soil, than in that upon which their fortifications were constructed. The land is every where low, intersected by many rivers, which descend from the interior mountains; it abounds in plantations of trees, and more especially of the cocoa-nut tree, and affords a very pleasant prospect. The rivers render it extremely fertile, particularly in rice; the sea furnishes a copious supply of fish, and provisions are cheap. The seasons are distinguished into the dry and rainy, called the bad and good monsoon; the former being reckoned from October to April, and the latter comprehending the other months. This division is occasioned by the mountains of the Ghauts; for upon the coast of Coromandel, the reverse takes place with respect to the monsoons.

The first and principal article of trade produced upon the coast of Malabar is pepper, which is very abundant, and reckoned the best in Asia. The Areca nut is the second production of the country; and this is conveyed by land to all parts of the peninsula, and likewise by sea, to the coast of Coromandel, and to Bengal. A third production is the wild cinnamon (*Cassia lignea*), of which it is said that a quantity of one million of pounds is yearly exported to the gulf of Persia, and to the Red sea; and a small proportion is sent to Europe, where it is principally used to adulterate the genuine, or Ceylon, cinnamon. Coarse cotton cloths are also made in the southern parts, in the Travancore country, which, without forming a considerable object of trade, were mostly

mostly disposed of to the English at Ansjengo. Capok forms also an article of trade, and is exported to Bengal, to the coast of Coromandel, and to China.

The native inhabitants of the country are inclined to be lean; they are usually of the same size and stature as the Gentoos at Surat and in Bengal; but they are much blacker, nearly as black as the African negroes, though with better formed countenances. Their religion is that of the Hindoos, but many of them have been converted by missionaries to the Roman Catholic persuasion, and they have many Roman Catholic churches. Here are also many Christians, of those denominated Christians of St. Thomas. Among the Malabars, the "Nairs" are the nobles and warriors of the land, who are distinguished by the scymetar which they always wear, and who possess many privileges above the common people. Their princes possess almost an absolute authority over their subjects. Besides the original Malabars, many other people have been allured to settle here, by the profits of trade; such as Moors, Arabians, Persians, and a colony of Jews, who, as they pretend, are the posterity of the ten tribes carried away into captivity by Shalmaneser. These dwell in a separate town, in which are three synagogues. The towns, or villages, which they inhabit, and where they are employed in trade, has received the appellation of "Makwan-Sieri."

Cranganore was sold by the Dutch to the king of Travancore, taken from him by Hyder Ali, and re-taken by the English in 1790. Cochim, Quilon, Quila-Quilon, and the other settlements of the Dutch, on the coast of Malabar, have shared the fate of the greater part of their Indian possessions, and are actually in the hands of the English.

MALABAR, Cape, or Sandy Point, a narrow strip of land, projecting from the S.E. part of Cape Cod, in the Massachusettses, eight miles S. by W. N. lat. $41^{\circ} 33'$. W. long. $70^{\circ} 3'$.

MALABAR Nut, in *Botany*, a species of the *justicia*; which see.

MALABATHRUM, among the *Ancients*, an excellent sweet-scented ointment.

MALABATHRUM, Indian leaf, in *Botany*. See **TAMALAPATRA**.

MALABRIGO, in *Geography*, a harbour on the coast of Peru, in the South sea.

MALACATLAN, a town of Mexico, in the province of Mechoacan; 16 miles S.E. of Colima.

MALACCA, or MALAYA, a peninsula of Asia, at the extremity of the kingdom of Siam, surrounded by the sea, except at its junction with this kingdom. The northern limits are not strictly defined; but the peninsula is reckoned to be about 80° , or 560 British miles in length, and in medial breadth about 150 miles. It derives its name from the Malays, who are mostly Mahometans, and in a considerable degree civilized; but the inland parts seem to be possessed by a more rude native race, of which our knowledge is very imperfect. In the last century Mandello, or rather Olearius, who published his voyage, describes Malacca as divided into two kingdoms, that of "Patani" in the north, and that of "Johor" in the south. The former was inhabited by Malays and Siamese; who were by profession Mahometans, and tributary to Siam. The town is built of reeds and wood, but the mosque of brick; and the commerce was conducted by the Chinese and Portuguese settlers, while the native Malays were chiefly employed in fishing and agriculture. From this traveller we learn, that in Malacca there are continued rains with a N.E. wind during the months of November, December, and January. Agriculture was con-

ducted with oxen and buffaloes, the chief product being rice. Game and fruits were abundant, and the forests swarmed with monkies, tigers, wild boars, and wild elephants. Besides the tiger and elegant, Malacca produces the civet-cat, and Sonnerat says that wild men are found here, meaning perhaps orang-outangs. Some singular birds are also found; and it likewise produces a delicious fruit called the Mangofiten. The Portuguese were accustomed to purchase annually from Patani about 1500 cattle for their settlement at Malacca. The kingdom of Johor comprehended the southern extremity of the Chersonese, and its chief towns were Linga, Bintam, Carimon, and Betufabea, the last of which was the capital, situated in a marshy situation, on the river Johor, about six leagues from the sea, and consisting of houses elevated about eight feet from the ground. The whole of this country belonged to the king, who assigned lands to those who demanded them; but the indolence of the Malays left it to the wild luxuriance of nature. According to the account of Valentyn, the peninsula of Malacca is bounded on the north by the river Riadang, which runs by Linga to the east, and by a small range of hills that separate it from the kingdom of Siam; and it contained five provinces, which derive their names from their capitals. On the eastern coast are those of Patani and Pahang, followed by the most southern kingdom of Djohor or Johor; and on the western coast are those of Keidah, or Quedah, and Perah, followed by another province called the Malay coast, and of which the capital is Malacca. The inland part of the peninsula seems to remain full of extensive and original forests, without towns or villages; but the country, though not sufficiently explored, is now known to produce pepper and other spices, with some precious gums and woods. The chief mineral is tin, in which Quedah and Perah, as Hamilton denominates them, are rich; and a high mountain N.E. of Malacca supplies rivers that afford small quantities of gold dust. In the river Pahaung, flowing near the town of Malacca, lumps of gold about five or six ounces in weight have been found at the depth of from three to ten fathoms. Of the government of Malacca we may form an idea from the account which Mr. Marfden has given of that of the Malays in Sumatra. See **MENANGEBOW**.

From an account of the ancient history of this country, cited by Valentyn in his "Description of the Dutch Settlements in the East Indies," 1726, from a Malay MS. written in the Arabian character, we are led to believe, that the Malays were first settled on the eastern coast of Sumatra, in the kingdom of Palambang, opposite to the isle of Banca, at the river Malajee, which encircles the mountain Mahameirac, and afterwards joins the river Tatang. Some have supposed that the river derives its name from the Malays; but Valentyn is of opinion that they derived their name from the river, and communicated it to their present peninsula, which formerly belonged to the king of Siam, and was inhabited by fishermen. This MS. being recent, we can only infer from it that the Malays came from the west. The traditions founded on this and other similar MSS. report, that the Malays, during their residence in Sumatra, chose a king, who reigned 48 years, and pretended to be a descendant of Alexander the Great. This happened about the year 1160 of the Christian era. During this reign, it is said, the Malays proceeded to the opposite coast and settled on the N.E. corner, whence they gradually spread, and the country assumed the name "Tanah Malajee," or Malay land, extending from 2° to 11° N. lat. After a residence of some years, the Malays built their first town "Singapoera," which gave its name to the southern strait.

strait. The last king of Singapoera was compelled by a hostile sovereign of a district in the isle of Java to retire northward, where, in the year 1253, he built a new capital, called Malacca, as it is said, from the name of a tree, the Mirabolan, under which he had taken shelter, while he was hunting. Having established salutary laws, he died in the year 1274. As this king had adopted the appellations "Shah" and "Sultan," it furnishes a presumption, that Mahometanism was now introduced. The second in succession after this prince, who is esteemed the first Mahometan sovereign, reigned 57 years. He extended more widely the name of Malays, and having acquired by marriage the kingdom of Aracan, he died in 1333. In process of time, the commercial town of Malacca was regarded, with Madjapit and Pofi, as the third celebrated city in these regions. Sultan Mantsoer Shah, who ascended the throne in 1374, and in the course of his long reign of 73 years, annexed by marriage the kingdom of Andrigiri on the E. side of Sumatra, to Malacca, became so powerful that he was styled emperor. In consequence of an alliance with the emperor of China, whose daughter he married, he subdued the kingdom of Pahang. Malacca was now esteemed the chief city in these parts of the eastern world. Mantsoer died in 1447. During an inglorious reign of his son and successor, the 11th king of the Malays, the 6th of Malacca, and the 5th who professed the Mahometan religion, Malacca became subject to Siam; but at his death, in 1477, he was succeeded by a prince, under whose government, in the year 1509, the Malays threw off the yoke of Siam. It was in this year that the Portuguese discovered Malacca, to which they were led by the vain idea of finding the golden Chersonese of the ancients.

With this view Emanuel, king of Portugal, sent out a fleet of 16 ships under the command of Sequeira. Among the officers of this fleet was Magalhaens or Magellan, who afterwards became famous as the first circumnavigator of the globe. Many attempts were made to assassinate Sequeira, and finding it impossible to make a commercial arrangement advantageous to his country, he returned to Portugal. At this time Albuquerque (see his article) was the Portuguese viceroy in the East Indies. On the 11th of August, 1511, he arrived before Malacca with a powerful fleet, while the king of Pahang was in the town on occasion of celebrating his nuptials with the daughter of sultan Mahmud Shah, the sovereign of the peninsula. Malacca was taken by storm; and the king fled to Johor, where he founded a new town and kingdom. The Portuguese, having gained complete possession of Malacca, formed an alliance with Siam. The king of Johor died in 1513, and was succeeded by his son sultan Ahmud Shah, who afterwards made a treaty with the Portuguese. Among the Portuguese governors of Malacca was Peter Mascarenhas in 1526, from whom was, probably, derived the name anciently given to the isle of Bourbon. During the reign of a sovereign, called Alawoddin, who took possession of the throne in 1591, the Dutch arrived, and formed an alliance with this prince against the Portuguese. In 1606 the Dutch, in conjunction with the king of Johor, attacked Malacca; and they made various attempts in succeeding years to gain possession of the country. But they were obliged to content themselves with a factory in Johor. At length Anthony Van Diemen, the famous governor-general of the Dutch settlements in the East Indies, finding a favourable opportunity for the execution of his purpose, dispatched in June 1640, a fleet of 12 ships and six sloops to blockade Malacca; and these were joined by about 20 small vessels of Johor. The Dutch soon erected a battery, and the siege was accompanied with famine and pestilence. In Janu-

ary, 1541, the famine was so severe, that the inhabitants were obliged to expel their women and children. The Dutch also suffered much from heat and fatigue; and at length impatience and desperation produced a general assault, which was executed on the 14th of January; and the governor capitulated. Valentyn reports, that during the siege more than 7000 died in the town, and a greater number found means to escape. The Dutch lost about 1500, chiefly by the plague. Thus the Portuguese, after a possession of nearly 130 years, lost this valuable settlement, then esteemed, after Goa, the richest in the East Indies. Malacca, which is represented as a strong place, was taken possession of by the English in August 1795. The Malay empire is now added to the dominions of Great Britain in the East by the capture of Java, in consequence of which Britain is become the mistress of the whole of the Malayan Archipelago.

The Malays, whose origin is not satisfactorily ascertained, are in general a well made people, somewhat below the middle stature. Their limbs are small, but well shaped, and they are particularly slender at the wrists and ankles. Their complexion is tawny, their eyes large, their noses seem to be flattened more by art than nature; and their hair is very long, black, and shining. They are reckoned the most ingenious, sagacious, and polished people in the East Indies. As the Malays resemble the Chinese and Tartars in their features, it has been suggested as probable that they are descended from those nations. Their progress from Malacca, across the narrow strait of that name, to Sumatra, from thence to Java, and from Java to all Polynesia, was so easy, even in the most frail vessels, that there is no difficulty in accounting for their being found, as they really are, in possession of the sea-coasts of almost every island. Mr. Marsden, in the last edition of his valuable work, seems to have retracted the opinion which he once held of Malacca being the original country of the Malays, and to think that they passed thither from Sumatra. Not only their physical appearance, but their manners and customs, as well as language, have undergone a considerable change by the overwhelming influence of the Arabs, who from the 9th to the 14th century, appear to have enjoyed the exclusive commerce and dominion of the oriental islands, the greater part of which has received the religion of Mahomet. These people in former times possessed great powers, and made a very considerable figure on the theatre of Asia; and their country was well cultivated and populous. The sea was covered with their ships, and their commerce was very extensive. At different times they sent out various colonies, which in succession peopled a great part of Sumatra, Java, Borneo, Celebes, and Macassar, the Moluccas, the Philippines, and those innumerable islands of the Archipelago, which bound Asia on the E. and which occupy an extent of 700 leagues in longitude from E. to W. and about 600 in latitude from N. to S. Every where the people seem to be the same. They speak almost the same language, and they have the same laws and the same manners. To this purpose Kæmpfer says in his "History of Japan," that the Malaysians had in former times the greatest trade in the East Indies, and frequented with their merchant ships not only all the coasts of Asia, but ventured even over to the coasts of Africa, particularly to the great island of Madagascar. That the Malaysians have not only frequented Madagascar, but that they have been the progenitors of some of the present race of inhabitants, is confirmed by the testimony of M. de Pages, who visited that island so late as 1774. The title which the king of the Malaysians assumed to himself, says Kæmpfer, of "Lord of the Winds and Seas

to the East and West," is an evident proof of their extensive migration; but much more the Malay language, which spread almost all over the East, much after the same manner as formerly the Latin, and of late the French, did all over Europe.

M. le Poivre, cited by Mr. Pennant in his "Outlines of the Globe," says, that travellers, who make observations on the Malays, are astonished to find in the centre of Asia, under the scorching climate of the line, the laws, the manners, the customs, and the prejudices of the ancient inhabitants of the north of Europe. The Malays are governed by feudal laws, "that capricious system, conceived for the defence of the liberty of a few against the tyranny of one, whilst the multitude is subject to slavery and oppression." Thus we have here a chief, who has the title of king or sultan, issuing his commands to his great vassals, who obey when they think proper; these have inferior vassals whose conduct is similar to that of their superiors. The "Oramcai," or noble, forming a small part of the nation, live independent, and sell their services to those who are disposed or able to give them the best price; whilst the body of the nation is composed of slaves, and lives in perpetual servitude. With these laws, says M. le Poivre, the Malays are restless, fond of navigation, war, plunder, emigrations, colonies, desperate enterprises, adventures, and gallantry. They talk incessantly of their honour and bravery, whilst they are universally considered by those with whom they have intercourse as the most treacherous and ferocious people on the face of the globe; and yet, which appears extremely singular, they speak the softest language of Asia. The ferocity of the Macassars is the reigning characteristic of all the Malay nations, and as an evidence of their faithlessness and treachery, it is alleged, that their treaties of peace and friendship never subsist beyond that self-interest by which they were induced to make them; and they are almost always armed, and either at war among themselves, or employed in pillaging their neighbours. Their ferocity, misnamed courage by the Malays, is so well known to the Europeans who have settlements in the Indies, that they have universally agreed in prohibiting the captains of their ships, who may put into the Malay islands, from taking on board any seamen of that nation, except in the greatest distress, and then on no account to exceed two or three. It is not uncommon for a few of these horrid savages suddenly to embark, attack a vessel by surprise, poignard in hand, massacre the people, and make themselves masters of her. Malay barks, with 25 or 30 men, have been known to board European ships of 30 or 40 guns, in order to take possession of them, and murder with their poignards great part of the crew. Those Malays who are not slaves always go armed; and they would think themselves disgraced if they went abroad without their poignards, or crissies.

The attire of the males consist of pantaloons with a wide robe of blue, red, or green; the neck is bare, but the head is covered with a turban. The female dress, like that generally used in the East Indies, is a long narrow petticoat, reaching from the breast to the feet, whilst the other parts are naked, and the hair is comely tied. The women are reckoned more intelligent than most others in the east, and their conversation is of course sensible and agreeable.

The other inhabitants of Malacca are Portuguese, Moors, and Chinese, and some settlers from Bengal and Guzerat. The chief articles of commerce are azel wood and camphor from the kingdom of Pahang; tin, gold, pepper, pedra de porco, and ivory. The manufactures are various articles of dress, worn here and in Hindoostan, cottons, chintz, &c. and some articles of copper. When Malacca came into the possession of the Dutch, the Dutch East India

company appointed the governor, under whose control were several factories, some in the peninsula, and others on the coast of Sumatra. The factories are those of Peirah, or Perah, on the Malay coast, for the tin trade; of Keidah, or Quedah, on the same coast, for carrying on commerce with the petty king of Xeedah, for tin, gold, and ivory; of Oedjan-Salang, for tin and ivory; of Andrigiri, on the coast of Sumatra, for pepper and gold. The Dutch also traded with Ligor and Tanaferim, in the dominions of Siam, for tin; and with Bangkoelo, for gold and pedra de porco before the English established themselves there. The island Dending was also considered as a dependence of Malacca.

The language of the Malays, which is original in the peninsula, has been called the Italian of the east, on account of the melody of its frequent vowels and liquids, and the infrequency of any harsh combination of mute consonants. Their character is the Arabic. Mr. Marsden could never discover that the Malays have any original written characters peculiar to themselves, before they acquired those now in use; though it is possible that such may have been lost. The adoption of the Mahometan religion has occasioned an influx of Arabic words into their language: the Portuguese have also furnished them with many new terms. They write on paper with ink of their own composition, and pens made of the twigs of a tree. The purest Malay is supposed to be spoken in the peninsula, and it has no inflexions of nouns or verbs; and, consequently, no cases, declensions, moods, or conjugations; all which inflexions are performed by the use of certain words expressive of a determinate meaning. The Malay language, or that which may be considered as its radix or foundation, has branched out into various dialects, that have been extended to all the islands of the eastern sea; from Madagascar to the remotest of Capt. Cook's discoveries, comprehending a wider extent than the Roman or any other tongue has yet boasted.

Of the connection and similarity of these various languages, Mr. Marsden has exhibited indisputable examples in a paper addressed to the Society of Antiquaries, and published in the "Archæologia," (vol. vi.) In different places it has been more or less mixed and corrupted, but between the most dissimilar branches, an evident sameness of many radical words is apparent, and in some, very distant from each other in point of situation, *e. g.* the Philippines and Madagascar, the deviation of the words is scarcely greater than is observable in the dialects of neighbouring provinces of the same kingdom. See Marsden's History of Sumatra, and Dictionary.

In the third volume of the "Asiatic Researches" (p. 11 and 12.) sir William Jones has pointed out, in a clear and decided manner, the connection between the Malayan and Sanscrit languages; and Mr. Marsden (Id. vol. iv. p. 217.) observes, that the Malayan is indebted to the Sanscrit for a considerable number of its terms. This ingenious writer conceives, that the intercourse by which this communication was effected must have taken place in times anterior, probably by many centuries, to the conversion of these people to the Mahometan religion; and before a great number of Arabic words, borrowed from the Koran and its commentaries, were introduced into the language. Our author, however, does not imagine, that the affinity between these languages is radical, or that the names for the common objects of sense are borrowed from the Sanscrit. The Malayan, as we have already stated, is a branch or dialect of the widely extended language prevailing throughout the islands of the Archipelago, called the "Malay-archipelago" and comprehending the Sunda, Philippine, and Molucca islands, in the maritime parts of which the Malayan is used

as a "lingua franca," and also those of the South sea, including, between the farthest limits of Madagascar on one side and Easter island on the other, the space of full 200 degrees of longitude. This consideration alone is sufficient to give it claim to the highest degree of antiquity, even to originality, as far as that term can be applied. The various dialects of this speech, though they have a wonderful agreement in many essential properties, have experienced those changes, which separation, time, and accident produce; and in respect to the purposes of intercourse, may be classed into several languages, differing considerably from each other. The marks of cultivation which distinguish the Malayan from his ruder neighbours, are to be attributed, in the opinion of Mr. Marsden, to the effects of an early connection that must have subsisted between the inhabitants of this eastern peninsula, and those of the continent of India. The Malayan, as he conceives, has not received any portion of its improvement, except from the genuine Hinduee of the northern provinces, prior to its debasement by the mixture of Arabic nouns, and the abuse of verbal auxiliaries. If the communication should be supposed to have its origin in commerce, our author inclines to consider the people of Guzerat, notwithstanding their distance, as the instructors of the Malays; as it is well known that the Hindu language has been preserved with greater purity in that, than in any other maritime province of India. The probability is strong, that the inhabitants of the Malay peninsula were in possession of an alphabet, of the same model with that of the Hindus, and were even skilled in composition, before the Mahometans introduced their learning and character among them. Frequent allusions to the most celebrated works of the Hindu mythological poets, especially the Mahabharat and the Ramayan, occur in the Malay writings; and these allusions imply that translations of the works were formerly in the hands of the Malays.

The Malayan language possesses, as we have already observed, a smoothness and sweetness of sound, rendering it well adapted to poetry, to which the Malays are passionately addicted. They amuse all their leisure hours, including the greater portion of their lives, with the repetition of songs, which are, for the most part, proverbs illustrating, or figures of speech applied to, the occurrences of life. Some, which they rehearse in a kind of recitative at their bimbangs, or feasts, are historical love tales, like our old English ballads, but often extempore. There are numerous works written in the Malay language, besides historical ballads, or songs on national traditions. See the writers already cited, and Pinkerton's Geog. vol. ii. For an account of the Malays of Ceylon, see Percival's Ceylon.

MALACCA, the chief town of the country above described, situated on the Malay coast, about eight leagues from the island of Sumatra. N. lat. $2^{\circ} 12' 6''$. E. long. $102^{\circ} 8' 45''$. It is situated partly upon a hill, and partly on level ground, which is low, wet, and unhealthy. Its circumference is about 1800 paces, and towards the sea there is a strong wall, about 600 paces long, and also another by the side of the river. Its fortifications have long since been considerably decayed. The adjacent country is so flat, that the sea shore is dry to a considerable distance at low water, and the shore is difficult of access, on account of the softness and muddiness of the bottom. The jurisdiction of the town is about 30 miles in length, and from eight to ten in breadth. Two small isles, called "Ilha des Naos" and "Ilha des Padras," at a small distance supply clay for bricks; and formerly the Portuguese vessels used to anchor between them. Two rivers are contiguous to the town; one on the N. called Cryforant, and another on the

S. which is more considerable, called Pahaung. The shape of the town, which presents many broad straight streets, is that of a crescent.

Before the conquest of the Portuguese, Malacca was a fishing town; it afterwards contained 11,000 inhabitants; but in the time of Valentyn, the number had decreased to between two and three hundred Dutch, Portuguese, and some Malays in huts at the extremities of the town, who possessed some plantations in the vicinity. Around the town are woods infested with wild beasts, especially tigers; and elephants are very numerous. This city was founded by the Mahometans in the 13th century, and held by the Portuguese till 1641, when it was seized by the Dutch. It gained great importance from its advantageous position for Indian and Chinese commerce. See the preceding article.

MALACCA, *Strait of*, the narrow sea between the island of Sumatra, and the peninsula of Malacca, extending from the equinoctial line to about 5° N. lat. This strait presents favourable opportunities for commerce, which has been maintained for a long time, and in a considerable degree, with Bengal, Coromandel, Surat, Persia, Ceylon, Java, Sumatra, Siam, Tonquin, China, and other places. This was a convenient station for the vessels passing through the strait from Japan to Hindoostan, and some chose this route to Batavia. In this strait provisions are scarce, except fish and a few fruits.

MALACCA Stones, a name given by many authors to the *pedr del porco*, or hog-bezoar.

MALACHE, formed of *μαλασσω*, *I soften*, a term used by authors in a different sense; sometimes expressing such medicines as gently loosen the belly, and sometimes such ointments as relax and mollify.

MALACHI, *the Prophecy of*, is one of the canonical books of the Old Testament, written by Malachi, who, according to a tradition among the ancients, was of the tribe of Zebulon, and born at Sapha, after the return of the captivity from Babylon, and who died young. He was probably contemporary with Nehemiah, and must have lived after the time of Haggai and Zechariah, because his prophecy supposes the temple to be rebuilt, and the worship of God established in it. Usher places him in the year 416, and Blair in 436 B.C. Some have doubted whether Malachi was a proper name, or a general appellation, signifying the angel or messenger of the Lord. Malachi, מַלְאָכִי, denotes "my angel;" but the LXX have rendered the word, his angel, and not my angel, as the original expresses it; and several of the fathers have quoted Malachi under the name of "the Angel of the Lord." It is the opinion of the ancient Hebrews, of the Chaldee Paraphrast, and of St. Jerom, that Malachi was Ezra. The chief corruptions which he charges upon the Jews are the same with those for which they were reproved by Nehemiah; he forbids them to expect any farther succession of prophets, exhorts them to observe the law of Moses, and predicts the coming of Elias, or John the Baptist, as the forerunner of the Messiah.

Bishop Lowth, in his "Prelections," says, that this book is written in a kind of middle style, which seems to indicate that the Hebrew poetry, from the time of the Babylonish captivity, was in a declining state, and being past its prime and vigour, was then fast verging towards the debility of age.

MALACHITES. See COPPER, *Ores of*.

MALACHODENDRUM, in *Botany*, so called by Mitchell and Cavanilles, from *μαλακος*, *soft*, and *δενδρον*, *a tree*, on account of its soft or downy leaves. Hence also the origin of *μαλαχη*, *a malloew*. This supposed genus differs in nothing from STUARTIA, to which we refer the reader, except in the separation of its five styles, which in the other

species are combined into one.—*M. corchoroides*, Mart. Mill. Dict. v. 3, is erroneously referred hither after Forkall, and is *Sida spinosa*, Vahl. Symb. v. 2. 78.

MALACHRA, like *Malacobodendrum* and other genera, owes its derivation to *μαλακος*, *soft*, or *delicate*, doubtless from the softness of its pubescence. Schreb. 464. Willd. Sp. Pl. v. 3. 768. Mart. Mill. Dict. v. 3. Juss. 272. Cavan. Diff. fasc. 2. 97. Lamarck Illustr. t. 580.—Class and order, *Monadelphia Polyandria*. Nat. Ord. *Columniferae*, Linn. *Malvaceae*, Juss.

Gen. Ch. *Cal.* Common Perianth large, bearing about five flowers, divided into three or five, heart-shaped, acute, permanent leaves: *proper* of one leaf, bell-shaped, small, five-cleft, permanent, set round with bristle-shaped scales. *Cor.* Petals five, obovate, entire, adhering below to the tube of the stamens. *Stam.* Filaments numerous, united below into a tube, gaping and loose above, over the whole surface of the cylinder; anthers kidney-shaped. *Pist.* Germen orbicular; style cylindrical, ten-cleft; stigmas globose. *Peric.* Capsules five, aggregate, roundish, compressed on one side, gibbous on the other. *Seeds* solitary, roundish, angular.

Ess. Ch. Common calyx of three leaves and many flowers, large. Capsules five, single-seeded.

Obf. Cavanilles has remarked, that, in *Malachra*, the divisions of the style and the stigmas are twice as many as the capsules.

1. *M. capitata*. Linn. Syst. Veg. ed. 14. 624. Willd. n. 1. Swartz. Obf. 262.—Stem rough. Flowers seven in a head. Leaves somewhat heart-shaped, slightly lobed.—A native of marshy places in the Caribbee islands.—*Stem* thick, erect, two feet high. *Leaves* stalked, furnished with awl-shaped stipulas. *Flowers* aggregate, sessile, yellow.

2. *M. fasciata*. Willd. n. 2. Jacq. Ic. Rar. v. 3. t. 548.—*Stem* villose. Flowers about five in a head. Leaves roundish, somewhat lobed.—A native of the Caraccas.—*Stem* six feet in height, remarkably rough, with rigid hairs. *Leaves* on long, hairy footstalks, the lower ones five-lobed at the margin, the upper ones three-lobed. *Flowers* axillary, small, bluish-coloured on the outside; whitish, with purple streaks, within.

3. *M. alceefolia*. Willd. n. 3. Jacq. Ic. Rar. v. 3. t. 549.—Flowers about ten in a head. Leaves cordate, deeply five-lobed.—A native of Martinique.—*Stem* six feet high, upright, branched, hairy. *Leaves* alternate, heart-shaped at the base, veiny, widely spreading, obtusely ferrated or notched. *Flowers* axillary, rather small, of a deep yellow colour.

4. *M. radiata*. Linn. Syst. Veg. ed. 14. 624. Cavan. Diff. t. 33. f. 3. (*Sida radiata*; Linn. Sp. Pl. 965.)—Flowers many in a head. Leaves palmate.—Found at St. Domingo.—*Stem* six feet in height, tender, round, whitish-green, hairy. *Leaves* crenate, hairy, bright green. *Flowers* small, purplish.

5. *M. bracteata*. Willd. n. 5. Cavan. Diff. t. 34. f. 2.—Flowers many in a head, bracteated. Leaves palmate.—Native of America.—*Stem*, like the whole plant, very hairy. *Leaves* crenate, with seven deep, acuminate lobes. *Flowers* about fourteen in each head, whitish, streaked with red at the bottom.

6. *M. plumosa*. Willd. n. 6. (*Sida plumosa*; Cavan. Diff. t. 12. f. 4.)—Flowers many in a head. Leaves undivided, elliptical, toothed.—A native of the Brazils. *Leaves* truncated. *Involucrum* of many leaves, the outer ones elliptical and toothed, the inner linear and fringed.

MALACIA, *μαλακία*, nearly synonymous with *pica*,

and *vitta*, signifies a depraved appetite, which induces the patient to desire to eat things which are indigestible, and not capable of affording nutriment; or that sort of deprivation of appetite, which was formerly deemed a sort of privilege attached to the state of pregnancy in women, which induced them to long for some particular food, with extraordinary earnestness, and eat of it to excess. While the danger of refusing indulgence to these longings was held as an axiom, they appear to have occurred perpetually; but they are now generally treated with ridicule, and therefore are seldom heard of. See *PICA*.

MALACODERMATA, formed of *μαλακος*, *soft*, and *δερμα*, *skin*, in *Natural History*, a term used to express such animals as have only soft skins for their covering; in opposition to the ostracodermata, which have hard shelly matters for their covering, such as crabs, lobsters, &c.

MALACOIDES, in *Botany*. See MALOPE.

MALACOLITE, in *Mineralogy*. See SAHLITE.

MALACOPTERIGII, in *Ichthyography*, the name of a large order of fishes, which have not prickly fins.

The term is derived from the Greek *μαλακος*, *soft*, and *πτερυγιον*, *a fin*. The fish of this order, are those which have bony fins, with all their extremities not pointed or sharp, but soft and harmless. Of this order are the carp, &c.

MALACOSTEON, (from *μαλακος*, *soft*, and *οσσειον*, *a bone*), in *Surgery*, a morbid softness of the bones. See MOLLITIES *Ossium*.

MALACOSTOMOUS, in *Ichthyography*, the name of a large genus of fishes, called in English the leather-mouthed kind. These fishes are wholly destitute of teeth in their jaws; but have them placed in their throats, near the orifice of the stomach.

The word is derived from the Greek *μαλακος*, *soft*, and *στομα*, *a mouth*. All the fish of this genus have their swimming, or air-bladder, divided into two parts; and of this genus are the carp, tench, bream, chub, and the like.

MALACOSTRACA, in *Natural History*, a term used by some, as Aristotle, to distinguish what we call crustaceous animals of the sea, &c. from those which he calls ostracodermata, or testaceous, as we express it. See table of testaceous and crustaceous animals. See CRUSTACEOUS.

MALACOTTA, in *Geography*, a town of Africa, in the country of Warada: the inhabitants manufacture soap from the oil of ground nuts: 42 miles E. of Satadoo. N. lat. 12° 30'. W. long. 9° 15'.

MALADUGNO, a town of Naples, in the province of Otranto; 9 miles N.W. of Otranto.

MALAGA, a small, but very ancient city of Spain, in the province of Granada. It was built by the Phœnicians several centuries B.C.; and it was called "Malacha," or "Malaca," on account of the great quantities of salt fish sold here. In process of time it passed successively under the dominion of the Carthaginians, Romans, Goths, and Moors. Strabo says, that a great quantity of salt was manufactured in its environs, which was disposed of on the opposite coast of Africa. That it was a place of importance under the Romans, we may infer from the wrecks of monuments that have been discovered in its vicinity. Some of these remains, which have been found on the eminences where the light-house is placed, and where the cattle called by the Moors Gibralfaro stands, have been thought to have belonged to a magnificent Pharos, or perhaps to a temple built on this spot by the Romans. It was not till the year 1487, that Ferdinand and Isabella recovered Malaga, after an obstinate resistance, from the dominion of the Moors. Malaga is situated on the coast of the Mediterranean, at the bottom of a deep bay,

on a foil of slate and limestone. To the south it has the sea: to the west it opens into a fertile plain, watered by two rivers; and to the east and north, it is protected by lofty mountains, the tops of which are sometimes covered with snow, and the sides with olive, almond, orange and lemon trees, and vineyard grounds. The town cannot be called handsome, though the houses are high: the streets are narrow, ill paved, and dirty; and it has not one good square. It has, however, a marble fountain, very finely executed, which was a present from the republic of Genoa to Charles I. The town has three fauxbourgs. It is the see of a bishop, suffragan to the archbishop of Seville, and the bishopric is worth 150,000 ducats, or 16,439*l.* 9*s.* 10*d.* but one-third of this revenue is disposed of by the king. The whole chapter consists of the bishop, with eight dignitaries, twelve canons, twelve minor canons, and the same number of prebendaries. The dean receives 600*l.* a-year; but the other dignitaries only 450*l.* The town has four parish churches, two chapels of ease, twelve monasteries, ten nunneries, four beaterios, six hospitals, and several chapels and oratories. Of the friars, the Franciscans take the lead, and are held in greatest veneration by the common people; and among these, the Capuchins are the most useful members of society, devoting themselves to the service of the poor. Malaga has a civil and military governor, a king's lieutenant, a major, aid-major, and a fixed regiment of infantry of three battalions, bearing its name and attached to the place; an alcade major for the administration of justice, a municipality composed of a certain number of regidores, a post-captain, a minister and an auditor of the Marine, and a board of public economy. This town has also a college for the instruction of youth, and another college, under the title of St. Elmo, for the instruction of mariners. The population of Malaga under the Moors, was reckoned at 80,000 inhabitants; and in 1747 it was reduced to 32,000; it is now estimated at 50,000, according to the statement of La Borde; but Mr. Townsend, in his "Travels," mentions the number at 41,592, of whom the greatest proportion consists of females.

Of the buildings, public or private, the only one, particularly worthy of notice, is the cathedral, begun in the year 1528, and, says Mr. Townsend, not yet completed. It is 360 feet by 180, and 135 in height. The choir in this edifice is admirable on account of its carved work, which represents, in very bold relief, the twelve apostles, and the most distinguished saints. The custom-house was erected on a magnificent plan in 1792. The consulate at Malaga have founded a very beneficial establishment, which is a "Mont de pieté," designed for lending money without interest to farmers, in order to prevent their selling their commodities, particularly wines, at a great loss. The funds of this institution arise from vacant benefices.

The port of this town is large and secure: it has water for first-rate ships of the line, and holds 400 merchant men, and 19 men of war. Ships may sail in and out with every wind, and are well sheltered in the harbour, particularly from the N. and E. winds, which are here the most violent. For greater safety two piers have been lately constructed. Malaga has a considerable trade, particularly with England. Its imports consist of broad cloths and iron ware, which it takes from the English; of mercery, from Germany, and more especially from Hamburg; and spices, cutlery, tapes, and laces, from Holland. It furnishes those countries, as well as Italy and the northern nations, with wine, fruits, sumac, anchovies, and oil. Its exportation of wine alone amounts to about 400,000 quintals yearly, and that of

raffins to 250,000 quintals. The amount of the imports is valued at 1,800,000 piastres, or 281,250*l.* sterling: that of the exports at 3,300,000 piastres, or 515,625*l.* sterling; so that the balance of trade is in its favour.

The soil in the vicinity of Malaga is fertile and well cultivated, producing great quantities of wheat and all sorts of grain; and olive trees are abundant, supplying 500 oil presses in this district alone. Fruit trees, such as the almond, fig, and lemon, are also very plentiful. The number of vineyards is immense, and they yield grapes of different species and of delicate quality. About 300,000 quintals are dried annually: 750,000 quintals of wine are made yearly; of which about 400,000 are exported. The vineyards are cultivated with great labour and expence; the expence, as stated by Mr. Townsend, being equal to $\frac{2}{3}$ ths of the produce. In the district of Malaga there are 14,000 wine-presses, chiefly employed in making the rich wines, which, from the nature of the country, is called *mountain*; if red, from the colour, *vino tento*, known to us by the name of "tent." The manufactures of Malaga, which are inconsiderable, consist of one for skins, leathers, and soles, and another of about 40 looms for silk stuffs, velvets, taffetas, serges, and silk cloth.

The inhabitants, blended with many foreigners, and occupying a beautiful country, in a mild climate and under a fine sky, are lively, industrious, and active. The men are polite and prepossessing: the women, lively, gay, and alluring, accounted the most agreeable in Spain.

MALAGA Bay, a bay on the east coast of the island of Leyta. N. lat. 10° 30'. E. long. 125° 12'.

MALAGMA, formed of *μαλασσω*, I soften, a word used by some authors to express a cataplasm in general, of whatever nature, or made of whatever ingredients; but some have used it only for emollient cataplasms.

MALAGRIDA, GABRIEL, in *Biography*, a native of Milan, and a member of the society of Jesuits, who was burnt at an "auto da fe," at Lisbon, in the year 1761, as an heretic and false prophet. He had been sent out as missionary to Portugal, where he became exceedingly popular, by his insinuating address, and the fluency of his oratory: he was venerated as a saint, and consulted as an oracle. When the duke d'Aveiro was convicted of a conspiracy against the life of the king of Portugal, Malagrida was accused of being an accomplice in the plot: he was pronounced guilty of the charges exhibited against him, but whether with or without justice is a matter of dispute; at any rate, advantage was taken of it to banish all the Jesuits from Portugal, excepting Malagrida and two others, who were reserved for punishment. To this probably the consent of the king could not be obtained, and, therefore, another method was adopted for getting rid of him. He was accused of heresy; in proof of which, two of his treatises were appealed to, *viz.* one entitled "Tractatus de Vita et Imperio Antichristi;" and the other, written in the Portuguese language, entitled "The Life of St. Anne, composed with the Assistance of the blessed Virgin Mary and her most holy Son." From these, several extracts were collected that were pronounced extremely heretical; and others were adduced to prove that he laid claim to the power of working miracles: and he also assumed that God himself had declared him his ambassador, his apostle, and prophet. He was burnt on the 21st of September 1761.

MALAGUETTA, in *Geography*. See GRAIN Coast.

MALAHA, a town of Perù, in the province of Parístan; 90 miles E. of Schiras.

MALAHIDE, a small town of the county of Dublin, Ireland,

Ireland, situate on the Irish sea. There is a well here, dedicated to the Virgin Mary; and also a castle, now the residence of the Talbot family. It is two miles E. from Swords.

MALAI, a town of Arabia; 15 miles S. of Medina.

MALAKERY, a town of Hindoostan, in Myfore; 21 miles N.E. of Seringapatam.

MALALAIS, a small island in the sea of Mindoro. N. lat. $11^{\circ} 18'$. E. long. $120^{\circ} 51'$.

MALALEO, a port on the north-west coast of the island of Tappa, in the East Indian sea. N. lat. $0^{\circ} 6'$. E. long. $123^{\circ} 35'$.

MALAMBETO, a town of South America, in the province of Carthagea; 40 miles E. of Carthagea.

MALAMBO, or BARRANCA DE MALAMEO, a town of South America, in the province of Carthagea; 55 miles N.E. of Carthagea.

MALAMOCO, an island in the Adriatic, about four miles long and half a mile broad, near the city of Venice; upon which island is a town of the same name, containing about 1100 inhabitants. Besides the cathedral, which is the parochial church, it contains a nunnery, a church, and some neat buildings. This was anciently the chief town of the Venetians, the residence of government, and the see of a bishop. The port of Malamoco is situated at the farthest point of the shore, towards Chioggia, and is defended by two forts, viz. St. Pietro and Della Punta. It is the safest and most convenient port, and therefore most frequented; but on account of its sand-bars and shallows, ships cannot enter into it without pilots. At this port was constantly garrisoned some thousands of regular troops.

MALANDERS, MALANDRIA, a disease in horses, so called from the Italian *malandare*, to go ill.

It consists in certain ulcerous chaps, or chinks, appearing on the inside of the fore-legs, just against the bending of the knee, which void a red, sharp, and pungent humour.

This distemper may be cured by washing the parts with a warm lather of soap, or old chamber-ley; and then applying over the cracks a strong mercurial ointment, spread on tow, with which they should be dressed night and morning, till all the scabs fall off; but if this treatment fail, make an ointment of half an ounce of æthiops mineral, one dram of white vitriol, six ounces of soft green soap; and having clipped off the hair, and cleared away the scabs, anoint often with this, and apply the above unguent over the sores. When they dry up, give a gentle purge or two; or let the nitre balls be taken for two or three weeks. Bartlet.

After washing the parts with soap and water, Mr. Denny advises to rub on a powder, made by mixing together vitriolated zinc and alum, of each pulverized half an ounce twice a day. Mr. White recommends the following ointment, prepared by mixing two ounces of ointment of wax, one ounce of olive oil, oil of turpentine and camphor, of each a dram, and two drams of acetated water of litharge. For the same purpose, Mr. Ryding recommends to mix one ounce of strong quicksilver ointment and ten grains of muriated quicksilver in fine powder.

MALANEA, in *Botany*, received its name from Aublet, but has been referred by Schreber and Willdenow to another genus *CUNNINGHAMIA* (see that article). Jussieu and Lamarck, however, retain the original name; but we are utterly incompetent to trace its derivation, of which Aublet himself gives no indication.

MALANEE, in *Geography*, a small island in the Florida stream. N. lat. $24^{\circ} 56'$.

MALANEO ISLANDS, two small islands in the North

Pacific ocean, near the east coast of the island of Luzon. N. lat. $18^{\circ} 2'$. E. long. $122^{\circ} 28'$.

MALANGER, a town of Norway, at the northern extremity of the diocese of Drontheim.

MALANOVA, a town of Russia, in the government of Tobolsk, on the Irtysh; 28 miles N. of Tara.

MALAO, a town on the north-west coast of the island of Mindanao.

MALAPERT, CHARLES, in *Biography*, a learned Jesuit and excellent mathematician, was born at Mons in the year 1581. He entered into the order in 1600, and was afterwards elected professor of mathematics in Poland; and he next filled the same office in the Jesuits' college at Doway. In 1630 he was appointed, by order of Philip IV., mathematical professor in the new university at Madrid; but he died on his journey to that capital, being in the 50th year of his age. While he was in Poland he published a volume of poems, which have gone through many editions; but his most important works were mathematical. In one, entitled "Oratio de Laudibus Mathematicis," he treats of the phenomena of the newly-discovered Dutch telescope. He published the "Institutions of practical Arithmetic," and the "Elements of Geometry;" "A Paraphrase on the Dialectics of Aristotle;" and "Commentaries on the first six Books of Euclid."

MALAR. See MÆLER.

MALARIA, or MALARUM OSSA, in *Anatomy*, a pair of bones belonging to the face, and corresponding in situation to the cheeks. See CRANIUM.

MALARMAT, in *Ichthyology*, a name given by authors to the fish called by some *lyra altera*, and *cornuta*. It is a species of the trigla, and is distinguished by Artedi by the name of the trigla with many cirrhi, and with an octagonal body. See TRIGLA *Cataphracta*.

MALARUM OSSA, in *Anatomy*. See MALARIA.

MALASHLAH, in *Geography*, a town of Africa, situated on the Atlas, in the southern part of Algiers; 170 miles S. of Algiers.

MALATIA, a town of Asiatic Turkey, in Aladulia, situated on the west side of the Euphrates; the residence of a Jacobite and Nestorian bishop. This town was taken in 1400 by Timur Bec. The Mussulmen redeemed themselves by money, and the Christians were made slaves; 90 miles W.N.W. of Diarbekir. N. lat. $37^{\circ} 56'$. E. long. 38° .

MALATIVOE, a fortified port of Ceylon, in a romantic and delightful situation, between Trincomalee and Jafnapatam. Here the Dutch had a small factory, and a house for the commanding officer. It depended upon the garrison of Trincomalee, and was employed chiefly as a port of communication, and to collect provisions for that garrison. For these purposes, and to keep the natives in awe, a few Malay or Sepoy soldiers were stationed here; but it never was considered as capable of any defence. Close to the fort is a small village; and a river, which here falls into the sea, forms a harbour sufficient to admit small craft. The principal employment of the inhabitants is fishing; and with this article they supply the fort of Trincomalee. Cattle and poultry are abundant and cheap. Game is plentiful, and the woods abound with wild hogs and deer. Percival's Ceylon.

MALATS, in *Chemistry*, are salts formed by the union of malic acid with alkaline, earthy, or metallic bases. See MALIC Acid.

MALATZKA, in *Geography*, a town of Hungary; 14 miles N. of Presburg.

MALAVERD, a town of Persia, in the province of Irak; 45 miles N.E. of Isfahan.

MALAUCENE, a town of France, in the department of the Vaucluse, and chief place of a canton, in the district of Orange; 14 miles E. of Orange. The place contains 2506, and the canton 5458 inhabitants, on a territory of 185 kilometres, in 7 communes.

MALAVISTA, a town of the island of Cuba; 36 miles W. of Villa del Principe.

MALAXIS, in *Botany*, a name applied by Professor Swartz to this new and very distinct genus of the Orchis tribe, established by Dr. Solander and himself. The word, $\mu\alpha\lambda\alpha\chi\iota\varsigma$, expresses *softness*, and seems to allude to the delicacy of habit and structure which marks these plants.—Swartz *Ac. Holm.* ann. 1789. 127. t. 6. f. 2. ann. 1800. 233. t. 3. f. P. Prodr. 119. *Orchid.* 68. t. 1. f. P. *Tracts on Botany*, 162. t. 5. Schreb. 603. Willd. *Sp. Pl.* v. 4. 80. Mart. *Mill. Dict.* v. 3. *Sm. Fl. Brit.* 940. Michaux *Boreal-Amer.* v. 2. 157.—Class and order, *Gynandria Monandria*. Nat. Ord. *Orchideæ*, Linn. Juss.

Gen. Ch. *Cal.* Perianth reversed, three-leaved, more or less acute, spreading, permanent, two upper leaves equal; lower solitary, in front, deflexed. *Cor.* permanent. Petals two, linear, deflexed, spreading, smaller than the calyx. Nectary an ascending or erect lip, between the two upper calyx-leaves, embracing the organs of fructification with its concave base, its termination obtuse or acute, undivided or slightly lobed. *Stam.* Anther an hemispherical, deciduous, obliquely terminal lid, of two cells; masses of pollen solitary, sessile, oblong or globular, lying on the anterior margin of the top of the style. *Pist.* Germen inferior, either oblong, somewhat cylindrical, or obovate, erect, slightly gibbous, excavated in front and at the summit; style erect or ascending, short and thick; stigma on the side towards the lip, beneath the anther, concave. *Peric.* Capsule oblong or obovate, with three or six ribs, of one cell and three valves, opening by clefts between the ribs. *Seeds* numerous, minute, each clothed with a chaffy tunic.

Eff. Ch. Calyx reversed, spreading. Petals deflexed. Lip ascending, concave at the base, without a spur. Anther a terminal lid, deciduous.

Obs. This genus is most allied to *Cymbidium* (see that article) in character, but differs in its reversed flower, as well as in its peculiar habit, indicated by the small, usually yellow or greenish blossoms, and a general delicacy of structure and texture. In what regards the habit of the flowers, however, independent of their posture, it must be confessed that *Cymbidium corallorrhizon* approaches *Malaxis* very nearly, though not at all in herbage.

1. *M. spicata*. Sw. n. 1.—Leaves two, ovate, shorter than their footstalks. Flower-stalk square, racemose. Lip obscurely three-lobed, pointed.—Native of Jamaica. The root is perennial, consisting of an oblong upright caudex, with numerous downy fibres, appearing to grow amongst rotten wood or leaves. Leaves two, radical, spreading, thin, delicate and pale, ovate, rather acute, entire, somewhat wavy, ribbed, smooth, about two inches long, each supported by a membranous, ribbed, tubular, sheathing footstalk, about three inches long. Flower-stalk about a foot high, solitary, radical, quadrangular, smooth, sheathed by the footstalks at the bottom, and terminating in a corymbose cluster of numerous, small, pale yellowish flowers, each of whose partial stalks is half an inch, or more, in length, and has at its base a linear, acute, membranous, permanent bractea. The lip is acute, with a small lobe at each side near the base, and has a dark central stripe. This seems to be the species which first caused the establishment of the genus; yet it does not well answer to the generic character in Swartz's *Prodrömus*, unless we conceive the central point of the lip to be

bent backwards, while the two lateral lobes, projecting forward, have a heart-shaped figure. The specific name is liable to objection, for the flowers are racemose, or corymbose, those of some other species being much more truly spiked.

2. *M. umbellulata*. Sw. n. 2.—Leaves two, ovate, shorter than their footstalks. Flower-stalks five-angled. Umbel dense. Lip obscurely three-lobed, pointed.—Native of Jamaica, apparently in similar situations with the foregoing, from which it differs chiefly in being of rather more humble stature, with smaller and greener flowers, growing in a little dense umbel, at the top of the pentagonal stalk.

3. *M. latifolia*. Leaves several, ovate, longer than their footstalks. Spike cylindrical. Bracteas deflexed. Lip three-lobed, the middle lobe largest.—Native of the woods of Upper Nepal; gathered by Dr. F. Buchanan, August 12th, 1802, at Narainhetty, where it is called by the inhabitants *Namly*. The root is like that of the former, with many strong, downy, twisted fibres. Leaves about four, on shortish, broad, ribbed, sheathing footstalks, broad-ovate, pointed, plaited, ribbed and striated, three or four inches long, being more than twice the length of their stalks. Flower-stalk central, solitary, above a foot high, erect, with several acute angles. Spike terminal, erect, cylindrical, dense, many-flowered, three inches long. Bracteas solitary, deflexed, awl-shaped, concave, membranous, permanent. Flowers sessile, small, yellow. Germen incurved, strongly furrowed, with crisped angles, its base tapering and elongated. Lower leaf of the calyx linear, reflexed at the sides, ascending at the point; two upper ones shorter, half-ovate and obtuse. Petals linear, widely spreading. Lip short, broad, erect, with three acute lobes, of which the middlemost is the largest, and entire, the side ones stained.

4. *M. odorata*. Willd. n. 6. (Katou-ponnam-maravara; Rheede Hort. Mal. v. 12. 55. t. 28.)—Leaves several, elliptic-lanceolate. Spike cylindrical. Bracteas deflexed. Lip heart-shaped, cloven at the point.—Gathered by Dr. Buchanan on the mossy rocks of Upper Nepal, where it is called *Bun Pinali*. Rheede says it loves sunny retired places, flowering in January and February, and having a very delightful smell. It has altogether the habit of the last, but the leaves are narrower, and more elliptical than ovate. The spike is longer, and flowers larger. The lip differs essentially, being of a broad heart-shaped figure, cloven half way down at the upper part, or point, which is obtuse, and embracing the organs of fructification between the bases of its rounded side-lobes. The flowers are altogether of a pale dull yellow, or buff-colour.

5. *M. Rheedii*. Swartz. n. 4. Willd. n. 5.—(Epidendrum repupinatum; Forst. Prodr. 61. Bafaala-poulou-maravara; Rheede Hort. Mal. v. 12. 53. t. 27.)—Leaves several, elliptic-lanceolate. Spike cylindrical. Bracteas deflexed. Lip inversely heart-shaped, rounded, fringed.—Native of the East Indies and the Society Islands, upon trees or rocks. We know it only by Rheede's and Forster's works. It is nearly allied to the last, and the flowers are said to be delightfully fragrant, but are essentially different from those of *M. odorata*, not only in being much smaller, and of a vermilion hue, but in the structure of their lip, which is inversely heart-shaped, its two rounded lobes being directed upwards; and their edge, moreover, is finely fringed.

6. *M. nervosa*. Swartz. n. 8. Willd. n. 10.—(Ophrys nervosa; Thunb. Jap. 27. Epidendrum nervosum; Thunb. Ic. Jap. t. 10.)—Leaves several, ovate, ribbed, acute. Stalk angular, racemose. Bracteas minute, spreading. Lip obovate, emarginate, reflexed, with a pair of tubercles at the

MALAXIS.

the base.—Gathered by Thunberg, flowering in May and June, near Osacca and Jedo in Japan, where it is called *Gin Ran*. It appears to differ from the last in having the *flowers* fewer, and much more distant, each supported by a slender partial stalk, forming a cluster, not a spike. By Thunberg's long and exact description it is evidently well referred by Swartz to this genus, with which its habit accords. The *calyx* consists of three equal linear leaves, two of which are lateral, the third lowermost. *Petals* lateral. *Lip* uppermost, twice as broad as the petals, obovate, emarginate, forming a sort of *galea*, bent backwards in the middle, marked with two callosities, and a furrow, at the base, without any spur. *Style* semi-cylindrical, curved upwards towards the lip. *Capsule* slender, twisted. The *flowers* are said to be purple, and the minute ovate *bractees* are of the same colour.

7. *M. lancifolia*. Leaves several, ovato-lanceolate, ribbed, acute. Flowers spiked. *Bractees* lanceolate, spreading. Lip obovate, abrupt, reflexed, convex.—Found by Dr. Buchanan in the woods at Suemba in Upper Nepal, July 17, 1802. Its affinity to the last did not escape its learned discoverer, but the present is rather a taller plant, being twelve or eighteen inches high. The *leaves* are much narrower and longer, about three or four in number, with long sheathing bases. *Stalk* angular, bearing a long slender spike of numerous green unspotted *flowers*, rather smaller than Thunberg delineates those of his *Ophrys nervosa*. The *bractees* are lanceolate, and nearly as long as the germens. The lip has no tubercles at its base, but is bent back towards the middle, as is *M. nervosa*.

8. *M. ophiolepis*. Willd. n. 3. (*M. unifolia*; Michaux Boreal-Amer. v. 2. 157. Swartz Orchid. 71.)—Leaf solitary, ovate, clasping the stem. Stalk with many angles. Lip cloven at the extremity.—Native of shady woods in North America. Sent from near Lancaster in Pennsylvania by the Rev. Dr. Muhlenberg. A delicate species, with much of the aspect of the two first, but distinguished from all hitherto discovered by its solitary leaf, which is ovate inclining to heart-shaped, acute, finely ribbed and reticulated, near an inch and a half long, clasping the stalk with its base, and sheathing two inches or more of the lower part with its clove, tubular, radical *footstalk*. The *flower-stalk* is solitary, rising four or five inches above the leaf, pale, slender, with several unequal angles not exactly five, and terminating in a very delicate corymbose cluster, of numerous small greenish *flowers*, on capillary stalks, with a small, ovate, acute, membranous *bractea* at the base of each stalk. Willdenow observed the lip to be cloven; and its lobes appear to us to be distant and divaricated, with a semi-circular sinus between them.

9. *M. monophyllos*. Swartz. n. 3. Willd. n. 4. (*Ophrys monophyllos*; Linn. Sp. Pl. 1342. Fl. Suec. ed. 2. 316. Wulf. in Jacq. Coll. v. 4. 340. t. 13. f. 2. O. monophyllos bulbosa; Loef. Pruss. 180. t. 57. O. lilifolia Suecica; Linn. Sp. Pl. 1341. n. 7. O. latifolia; Fl. Suec. ed. 2. 316. n. 811, on the authority of Dr. Swartz. Epipactis n. 1293; Hall. Helvet. v. 2. 151. t. 36.)—Leaf nearly solitary, elliptic-ovate. Stalk triangular. Lip undivided.—Native of boggy shady alpine places, in Prussia, Sweden, Russia, Carniola, and, though very rarely, in Switzerland, flowering in the spring. This is closely allied in habit to the last. *Root* an aggregate bulb, with numerous fibres, and invested with several ribbed sheaths, altogether more like an *Allium*, as Wulfen observes, than any of the *Orchis* tribe. Such, however, is the nature of all the foregoing species, as far as has been ascertained. One elliptical, delicately ribbed, leaf, acute at each extremity, and running

down into a long sheathing base, or radical *footstalk*, embraces the stalk, attended by one or two shorter external sheaths, and often accompanied by a much smaller internal leaf. The *stalk* is triangular, terminating in a long slender cluster, of very numerous small green *flowers*, with every character of the genus. Their *bractees* are like those of the last, but their lip is undivided, with a taper point. Dr. Swartz assures us the *Ophrys latifolia* of Linnæus's *Flora Suecica*, (erroneously so printed for *lilifolia*,) was no other than a specimen of the species we are describing, in which the second leaf was more remarkable than usual.

10. *M. paludosa*. Swartz. n. 5. Willd. n. 7. Sm. Fl. Brit. 940. Engl. Bot. t. 72. (*Ophrys paludosa*; Linn. Sp. Pl. 1341. Fl. Suec. 316. Rose Elem. of Bot. append. 450. t. 2. f. 3. Dickf. H. Sicc. fasc. 7. 16. Ehrh. Phytoph. 16.)—Leaves several, spatulate, rough at the tip. Stalk with five angles. Lip undivided, concave, half the length of the calyx.—Native of turfy bogs in the north of Europe, flowering in July. It is found in Cambridgeshire, Bedfordshire, and on Felthorpe bogs a few miles north of Norwich, though now far more rare than formerly, from the general improvement of such grounds by draining. This is perhaps the smallest species of its genus, or even of the whole natural order. The *roots* consist of little bulbs, connected by a thread-shaped fibre, and exactly accord with those of the foregoing. The *leaves* are about four, sheathing, an inch long, spatulate, firm and rather fleshy, jagged or rough at the point, slightly glaucous. *Flowers* in a long dense cluster, of a yellowish-green. *Calyx-leaves* nearly equal, ovate. *Petals* rather smaller, reflexed. *Lip* erect, ovate, concave, undivided, but half the length of the calyx. *Germen* obovate.

11. *M. lilifolia*. Swartz. n. 6. Willd. n. 8. (*Ophrys lilifolia*; Linn. Sp. Pl. 1341. Andr. Repof. t. 65.)—Leaves two, ovate. Stalk triangular. *Petals* linear-thread-shaped. Lip prominent, obovate, acute. *Style* deflexed, recurved.—Native of wet places in Pennsylvania. The late Peter Collinson cultivated it about 50 years ago, and plants are from time to time brought to England, though seldom long preserved. This and the two following belong to a tribe which have not so clearly the character of *Malaxis* as could be wished. The *flower* is seldom truly reversed, though more or less turned, and the lip, of the present species at least, is rather directed forward than upward, while the column, or *style*, though curved upward, stands opposite, not parallel, to the lip. The whole habit, however, agrees to entirely in every point with *Malaxis*, and with nothing else, that Dr. Swartz has finally determined to place them here, rather than in the less natural genus of *Cymbidium*; especially as the position of their flowers will very often excuse, if not justify, the measure. The *root* of *M. lilifolia* is an ovate bulb, with a spongy reticulated coat, and many woolly fibres. *Leaves* two, radical, three or four inches long, equal, opposite, ovate, keeled, ribbed, bluntish, embracing each other at the base, and accompanied by one or two broad, short, external, sheathing scales. *Stalk* erect, straight, about twice as tall as the leaves, triangular, furrowed, terminating in a loose upright cluster of numerous *flowers*, as large as those of most of our common *Orchideæ*. The *calyx-leaves* are linear, half an inch long, spreading, of a pale yellowish-green. *Petals* whitish, as long but much narrower, almost capillary, dependent. *Lip* rather longer than the calyx, olive-green, projecting, somewhat recurved, obovate with a small point, channelled at the base. *Style* incurved, with a hooked tip to the cover of the anthers. *Germen* slender, furrowed, gradually swelling upwards, twisted.

12. *M. cordifolia*. Leaf nearly solitary, heart-shaped. Stalk furrowed. Petals linear-thread-shaped. Lip prominent, inversely heart-shaped, with a small point. Germen acutely triangular.—Gathered by Dr. Buchanan, Oct. 2d, 1802; at Narainhetty in Upper Nepal. It grows in watery places, amongst dead leaves, in a micaceous soil. This is closely allied to the last, though abundantly distinct as a species. In size they exactly agree. The roots of the present have a thick, spongy, whitish coat, and very long woolly fibres. There is one principal leaf, which is radical, heart-shaped, pointed, ribbed, near three inches long and above two broad, with a shortish sheathing base or footstalk, enveloped in one or two scales. Sometimes, if not always, there occurs, as in *M. monophylos*, n. 9, a very small folded ovate leaf, in the bosom of the other. The flower-stalk is twice as tall as the leaf, loosely racemose. Flowers apparently very much like those of *M. lilifolia*, but the lip is obcordate with a small point, and the germen is very acutely triangular, becoming club-shaped as it advances, straight, not twisted, with three very evident membranous or winged angles. We have only seen one dried specimen.

13. *M. Loeffelii*. Swartz. n. 7. Willd. n. 9. (Ophrys Loeffelii; Linn. Sp. Pl. 1341. Sm. Fl. Brit. 935. Engl. Bot. t. 47. Dickf. H. Sicc. fasc. 9. 11. Ehrh. Herb. 110. O. lilifolia; Hudf. 389. O. paludosa; Fl. Dan. t. 877. O. diphyllus bulbosa; Loeff. Pruss. 180. t. 58. O. bifolia bulbosa; Ger. em. 403. Cymbidium Loeffelii; Swartz Nov. Act. Upsal. v. 6. 76.)—Leaves two, elliptic-lanceolate. Stalk triangular. Petals linear. Lip prominent, obovate, channelled, undivided, recurved.—Native of marshes on a sandy soil, among rushes, flowering in July, chiefly in the north of Europe. We have it in Cambridge-shire and Norfolk, but it is esteemed a rare plant, and considering its history and affinities, is certainly one of the most interesting in our British Flora. The habit of the roots, with their white spongy covering and woolly fibres, exactly accords with the two last described, and indeed with *M. paludosa*, n. 10. The leaves, however, are much narrower than in *lilifolia* or *cordifolia*, and more resemble those of Lily of the Valley. The flowers also are fewer and smaller, more frequently reversed, with broader petals, and a yellow, obovate, slightly wavy, but not divided, lip, opposite to which stands the incurved style. The germen is obovate, with six angles. The late Mr. Pitchford, who first met with this species in Norfolk, exchanged his only specimen with Mr. Lightfoot, for above 60 of the rarest British plants.

14. *M. ensiformis*. Leaves several, sword-shaped, equitant, ribless. Spike very long, dependent. Lip heart-shaped, four-lobed.—This grows parasitically upon trees at Narainhetty in Upper Nepal, where it was gathered by Dr. Buchanan, November 13, 1802. It is a genuine *Malaxis*, though different in habit from the usual aspect of the genus. The root consists of long, strong, woolly fibres, with scarcely any bulb. Leaves numerous, radical, two-ranked, equitant, sessile, a foot long, sword-shaped, very acute, coriaceous, quite smooth, without ribs, of a fine shining grass-green, separating, by age or drying, at a kind of joint near the base. Flower-stalk solitary, central, radical, roundish, longer than the leaves, terminating in an extremely long, recurved or pendulous, dense, cylindrical spike, of innumerable small flowers, of a dull orange hue. They are truly reversed, the calyx-leaves and petals ovate; the lip erect, longer than the petals; heart-shaped at the base, where it embraces the short erect style; four-lobed in the margin, the two middle lobes rather elongated. Germen short, elliptical, with six ribs.

Such are all the species that we can satisfactorily refer to this genus, not without scruples respecting the 11th, 12th, and 13th. Three others, indicated as doubtful by Swartz, and adopted by Willdenow, we presume, without the least hesitation, to exclude. These are

M. cernua, Willd. n. 11. (Béla póla; Rheede Hort. Mal. v. 11. 69. t. 35.)

M. nutans, ib. n. 12. (Limodorum nutans; Roxb. Corom. v. 1. 33. t. 40.)

M. caudata, ib. n. 13. (Epidendrum caudatum; Linn. Sp. Pl. 1349. Helleborine florum foliis maculosis et longissimis; Plum. Cat. 9. Ic. t. 177.)

Of these the two first, natives of the East Indies, appear to us to have the character of *Cymbidium*, (see that article,) and not in any manner to accord with *Malaxis*. With them certainly agrees in genus the *Limodorum recurvum*, Roxb. Corom. v. 1. 33. t. 39, L. n. 9. Willd. as well as *Epidendrum terriflorum* of the Linnæan herbarium, and a nondescript species from Dr. Buchanan.

The last, *E. caudatum* of Linnæus, a plant we believe known to Plumier only, does indeed, by his plate, seem to have the reversed flower of a *Malaxis*; but the habit is so different, and the figure is so incorrectly drawn, the calyx being represented interior with respect to the petals, and the column extremely various and confused, that we conceive nothing can safely be deduced from it. We will nevertheless venture to observe, that if this species be referrible, by its essential character, to *Malaxis*, some new one must be sought to define the genus, in order to exclude a plant so foreign to it, and which evidently belongs either to *Cymbidium* or *Dendrobium*. In such cases, however, no prudent botanist will truit to any figure, much less to so inaccurate an one as that before us, but will suspend his judgment till he can examine Nature herself. S.

MALAZKERD, in Geography, a town of Turkish Armenia, on the Aras; 140 miles N.E. of Diarbekir. N. lat. 39°. E. long. 41° 59'.

MALBARY, a town of Hindoostan, in Vissapour; 6 miles N.E. of Merritch.

MALBAY, a bay of the county of Clare, Ireland, on its west coast, which is deemed unsafe, and not frequented.—Also, a river of Canada, which runs into the St. Lawrence, 63 miles below Quebec.

MALCHIN, a town of the duchy of Mecklenburg, on the Cumber lake, at the mouth of the river Peene. The states assemble here once in two years; 26 miles S.E. of Rostock. N. lat. 53° 4'. E. long. 12° 32'.

MALCHOW, a town of Mecklenburg; 40 miles S. of Rostock. N. lat. 53° 30'. E. long. 12° 33'.

MALCOLM, ALEXANDER, in Biography, author of "A Treatise of Music, speculative, practical, and historical," thick 8vo., Edinburgh, 1721. This work, which has considerable merit, is dedicated to the most illustrious directors of the Royal Academy of Music. (See OPERA.) We are old enough to remember several of the illustrious personages who were subscribers to this establishment, yet never

never heard of any one of them that was likely to read this book, colonel Blathwaite and general O'Hara excepted: the first a dilettante of eminence; the second possessed of good taste, and, from hearing and comparing great performers and good compositions, an excellent judge of musical talents. The rest were pleased they knew not why, and were drawn into the vortex of fashion by example.

Upon a late perusal of this work, which we had not seen for near half a century, we find in it indisputable proofs of the author's learning, diligence, and knowledge. He has drawn from the purest sources of information concerning ancient music, and does not seem ignorant of the modern. His chapters on composition, however, go but a little way into the mysteries of the art. He has indeed given common examples of the three species of movement in melody: *retto*, *oblique*, and *moto contrario*; rising and falling together; one part stationary, and the other moving up or down; and contrary motion. He has also given the treble and base of a few usual cadences, in two parts only. But though his explanations, descriptions, and discussions are numerous, they are rendered so tedious and full of repetitions and amplifications, that many years study, experience, and reading, would be still necessary for a student, after the most careful and attentive perusal of this book, to render him a complete contrapuntist. His instructions are rendered obscure, perhaps, by too great a desire to render them clear: they are involved in too many words. "In vitium ducit culpæ fuga, si caret arte." The style is not alluring: it abounds in Scotticisms, is rough, and often dark and uncouth. The work is too scientific for an elementary treatise, and too superficial in the rules for practical harmony. We well remember, at an early stage of study, to have taken up this book with a sure and certain hope of finding in it a solution of all our doubts and difficulties; but soon laid it down in despair. The author seems to have begun at the wrong end of his labour, plunging into theory and speculation before he speaks of practice. The plates at the beginning have a hieroglyphic appearance, and must be totally unintelligible to inexperience; and the author seems deficient in that agreeable and fascinating manner of writing, in the lively strokes, and variety of occasional instruction, which Bayle allows even to his enemy, Maimbourg. "There are few historians," says he, "even among those who write better, and are more learned and exact, that have the art of engaging the reader's attention so much as he does." Though our author has read and meditated much, yet, by being self-taught, there is an awkwardness of expression in communicating his knowledge to his readers, which wanted practice and good taste to render it clear, useful, and pleasant.

As this work is become somewhat scarce, and was published before the Monthly and Critical Reviews were established, we shall specify some of the principal subjects which the author has treated, and the authorities upon which he builds. His doctrine of vibration is taken from s'Gravesande and Keil. He mentions Vincenzo Galileo, but not his more learned son. Kircher, Dr. Holder, and Dr. Wallis, are cited; the latter on his doubts concerning the vibrations which constitute intervals, from their celerity, as we are unable to count them. He considers ratios and coincidences under the guidance of Mercennus. He does not mention Galileo, in speaking of the doctrine of pendulums; nor does he give any authorities in explaining arithmetical, harmonical, and geometrical proportions. Kepler is quoted, and Des Cartes, on the geometrical part of harmonics by dividing right lines. He denominates the lowest sound of a common chord the *fundamental*, five years before it was used by Rameau as the generator of a chord.

VOL. XXII.

The word *concinuous*, so frequently used by Graffineau, seems adopted from Malcolm. Salmon's Temperament considered; and his proposal for reducing all classes to one, discussed and approved. Solmification, according to the hexachords, he severely censures. M. Laborde, in his "Essais sur la Mus.," has given a short article to this work, without saying who or what the author was; but in the index, he calls him "Ecrivain Francois sur la Musique." None of our biographical dictionaries have honoured him with the least notice; though he certainly ranks high among musical writers in our own language. Walther, however, tells us from Mattheson, that he was "ein geleheter Schottlandischer edilmann," a learned Scots nobleman. From the materials which he had collected, an ingenious and lively writer might have made a captivating and instructive work. The disciples of Dr. Pepusch, the only studious musicians of that time, condemned him for having disputed the utility of solmification and the mutations, according to the hexachords. But Chambers, in the first edition of his Cyclopædia, was indebted to Malcolm for most of his musical articles. And the French seem better acquainted with this book than the English, though we have never seen a translation of it in that language; yet, in Rousseau and others, we perceive a frequent anonymous use of this book. The author has indeed often availed himself of Perrault's philosophy of sound, but not without naming him. He denies music in parts to the ancients, and seems to have been one of the first writers on the subject, who dared to doubt that a music, capable of such miraculous effects as were ascribed to it, should be deficient in that part of modern music which affords us the greatest pleasure.

MALDA, in *Geography*, a town of Hindoostan, in Meerwar; 30 miles S.S.W. of Afsawully.

MALDE'E, a town of Persia, in the province of Segestan; 141 miles E.N.E. of Zareng.

MALDEN, or MALDON, an ancient and populous borough and market town in the hundred of Dengy, and county of Essex, England, is situated ten miles distant from Chelmsford, and 37 from London, on the acclivity of an eminence S.W. of the estuary of the Blackwater, or river Idumanum. Many of our ancient topographers assign this place as the Camalodunum of the Romans: but this subject has been fully investigated in the Beauties of England and Wales, vol. v. under COLCHESTER; which town see also in this work. The earliest mention of Malden, by historians, refers to the year 913, when Edward the Elder entrenched here to impede the progress of the Danes: the entrenchment he formed lies on the W. side of the town, and appears to have been of an oblong form, and to have inclosed about twenty-four acres: three sides of the ramparts may yet be traced; the other is defaced by buildings. Its strength was probably considerable, as in 921 a great army of Danes besieged it without effect. In 993 it was again attacked by the Danish forces commanded by Unlaf. In the Domesday Survey, Malden is styled a half hundred, and had then 180 houses, and a hall held by the burghesses of the king, who had also a house here in his own possession. When Malden was constituted a borough is uncertain: a charter appears to have been granted to the burghesses by Henry II. By another charter from queen Mary in 1553, the borough was incorporated, and its government vested in two bailiffs, six aldermen, and eighteen capital burghesses. Two members are returned to parliament; the right of election is confined to those who obtain their freedom by birth, marriage, or servitude; the number of voters is about 200. The first return was made in the year 1329. The custom of Borough-English, by which the youngest son succeeds to the burghage-tenement

tenement on the death of his father, still prevails here. The town consists of one principal street, extending nearly a mile east and west, a cross street of considerable length, and several smaller avenues and back lanes. The descent from the upper part to the river is very steep; many of the houses are respectable, having been rebuilt within the last fifty years. The import trade is considerable; consisting of coal, iron, deal, corn, &c. At spring-tides the river will bring up vessels that draw eight feet water; but the coals are brought to the town in lighters. Two fairs are held annually, and a weekly market on Saturdays. In the population survey of the year 1801, the number of houses was stated to be 454, inhabited by 2358 persons. Malden had formerly three parishes, but two of them have long been consolidated. The principal church, that of All Saints, is an ancient and spacious edifice, with a square tower terminated by a triangular spire: in the fourth, or d'Arcy's aisle, three chantries were founded in the reign of Henry VI. by Robert d'Arcy, esq. of Danbury, several of whose family were buried here. Near this church is the town-hall, which is a large and ancient brick building. St. Mary's church is a spacious pile, situated in the lower part of the town, and recorded to have been founded by Ingelric, a Saxon nobleman, previous to the Norman conquest: the tower, with part of the church, was rebuilt in the reign of Charles I. St. Peter's, the parish united to All Saints, had formerly a church, of which the tower only is now standing: attached to it is a building, erected by Dr. Thomas Plume, archdeacon of Rochester, for a grammar school and library. This gentleman was born at Malden in 1630, and in the latter part of his life became a great benefactor to his native town, as well as to several other places. The books contained in the library were his own collection, and are ordered to be lent out for general use. He appropriated the rents of a farm at Iltney, to keep the school and library in repair. He also gave 200*l.* to build a workhouse for the poor; and 1000*l.* more to establish the trade of weaving sackcloth to employ them. The Plumian Professorship of Astronomy and Natural Philosophy at Cambridge was founded by a bequest of 1902*l.* which he left for that purpose. He died in 1704.

Richard de Gravesend, bishop of London, about the year 1291, founded a small priory for Carmelites or White monks, in Malden, which continued till the dissolution. Several eminent scholars are mentioned by Ball and others, as having been inmates of this monastery.

In the forty-seventh volume of the Philosophical Transactions, is an account of Edward Bright, a shop-keeper of this town, who was so enormously fat, that his size and weight are almost unparalleled in the history of the human race. At the age of twelve years and a half, his weight was 144*lbs.*; increasing in bulk as he grew up, in seven years more he weighed 336*lbs.* He increased in bulk in nearly the same proportion, and at the age of twenty-eight his weight was 584*lbs.*: this was the last time he was weighed; but as he was manifestly bigger at the time of his death, his weight must then be upwards of 600*lbs.* His height was five feet nine inches and a half; and his circumference, round the belly, six feet eleven inches. He died in 1750, aged 29; after his death seven men were buttoned in his waistcoat. Till within a year or two of his death he was comparatively an active man; but afterwards his extreme corpulency rendered his life burthenfome. He left a widow pregnant of her sixth child.

Nearly one mile west from Malden stood Bileigh abbey, founded, in the year 1180, by Robert de Mantell, for monks of the Premonstratensian order. Some parts of the monastic buildings still remain, and are now connected with a

small farm. The chapel is the most perfect part; its roof is formed with very fine-grained lime-stone, and has groined arches, supported by three slender Purbeck columns. Henry Bourcher, earl of Essex, who died April 4, 1483, and Isabel his wife, were buried here. Beauties of England and Wales, vol. v. Morant's History, &c. of Essex, 2 vols. folio.

MALDEN, a town of the county of Zutphen; seven miles E. of Borckeloe.—Also, a town of America, in Middlesex county, Massachusetts, four miles N. of Bolton, containing 1059 inhabitants.—Also, a district or township of Essex county, in Upper Canada, occupying a considerable extent, and situated on the eastern side of Detroit river, about eighteen miles below the town of Detroit. At the lower end of the district there are but few scattered houses; but at the upper end, bordering upon the river, and adjoining to the new British post that has been established since the evacuation of Detroit, a little town has been laid out, which is rapidly increasing. Hither several of the traders have removed, who formerly resided at Detroit. This little town and the new post are denominated “The new British town and post near the island of Bois-Blanc,” an island in the river near two miles in length, and half a mile in breadth, that lies opposite to Malden.

MALDENANTRE, a small island near the coast of Sardinia. N. lat. 40° 1'. E. long. 8° 13'.

MALDIVES, a cluster of small islands in the East Indian sea, about 270 miles S.W. of cape Comorin, amounting in number, as it is said, to more than 1000, and mostly uninhabited. They form a kind of oblong inclosure, around a clear space of sea, with very shallow water between one another. According to Mr. Dalrymple's chart, they seem to be divided into thirteen groups, nearly equidistant, and each bearing its proper name. The inhabitants of those that are occupied appear to be a mixture of Arabs and Indians of Malabar, from which coast these islands probably were originally colonized. They were discovered in 1508 by the younger Almeyda, and conquered by the Portuguese from the Moors, who had usurped the sovereignty from the natives. The Portuguese, however, were soon cut off by the original Maldives. Among the inhabitants, who are governed by a chief called *Atoll*, who are miserably poor, and who are governed in an oppressive manner, there are some Mahometans. Their language is the Singalese: their articles of commerce are sails and cordage, cocoa-nuts, oil, honey, dry fish, tortoise-shell, and cowries, and these articles are collected in four ports. These islands lie in N. lat. 5° 30' to 7° 5'; and E. long. 72° 30' to 73° 45'.

MALDONADO, a town of South America, in the government of Buenos Ayres, on the river Plata; 100 miles W. of Buenos Ayres. S. lat. 34° 50'. W. long. 55° 36'.

MALDONAT, JOHN, in *Biography*, a learned Spanish Jesuit, was born near Lerena, in Estramadura, in the year 1534. He pursued his studies at the university of Salamanca, where he afterwards taught the Greek language and divinity with much success and applause. He assumed the habit of the order when he was at Rome, in the year 1562. In the following year he was appointed professor of philosophy in the college at Paris, which the Jesuits had just founded in that city; after this he commenced a course of divinity in the same seminary which occupied him four years. These lectures were attended by a prodigious concourse of scholars, who would assemble two or three hours before the time in which the lectures began to insure themselves places. In 1570 he was sent with nine other Jesuits to Poitiers, with the view of forming an establishment of the order in that city, but in this they were unsuccessful. He next re-

turned

turned to Paris, and resumed his lectures with great success, but in the midst of his labours he was interrupted by the exhibition of certain accusations against him, one of which was, that by his influence over the mind of the president St. Andre, he had obtained a fraudulent will, by which his estates were bequeathed to the Jesuits, and the other was an accusation of heresy, for maintaining that the doctrine of the immaculate conception of the Holy Virgin was not a point of faith. After a regular hearing he was acquitted of both these charges, but his mind was uninged, and he determined to relinquish his lectures, and to retire in a good measure from the world. In his retreat at the college of Jesuits at Bourges, he employed himself in commentaries on the scriptures, till he was called out of his obscurity by pope Gregory XIII., to superintend the publication of "The Septuagint," at Rome. Here also he finished his Commentaries on the Gospels, which was in 1582; and in the following year he fell sick, and died in the fifty-ninth year of his age. Maldonat was reckoned one of the ablest scholars of the society to which he belonged: he was a capital linguist, an eloquent preacher, and a judicious commentator on the scriptures. He is highly spoken of by Dupin, father Simon, and other learned men. Simon, in reference to his qualities as a commentator and critic, says, "he does not allow one difficulty to pass without examining it to the bottom. When a great number of literal interpretations of the same passage present themselves, he usually fixes on the best, without paying too much deference to the ancient expositors, or even to the majority, regarding nothing but Truth alone, stripped of all authorities but her own." The principal works of Maldonat are "Commentarii in quatuor Evangelistas;" "Commentarii in quatuor Prophetas, Hieremiam, Baruch, Ezekielem, et Danielem;" he was author of many other works, but they were all given to the world after the death of the author; and some pieces have been attributed to his pen, which were not only unworthy of his high reputation, but which have generally been regarded as spurious. Bayle. Moreri, &c.

MALDUAR, in *Geography*, a small circur of Bengal, between Dinagepour and Purneah, about nine miles long, and six broad; which may be considered as part of Rajemul. The chief town is Rahny.

MALE, the chief and most fertile of those islands called the "Maldives;" situated nearly in the centre of the group, about four miles in circumference, and containing a town, in which the princes reside. N. lat. $6^{\circ} 20'$. E. long. $73^{\circ} 10'$.

MALE, the sex which has the parts of generation without-side, and which has ordinarily the pre-eminence over the other.

In this sense male stands opposed to female.

For the proportion of males to females, see **MARRIAGE**.

MALE Balsam Apple, in *Gardening*. See **MOMORDICA**.

MALEBAYE, LA, in *Geography*, a town of Canada, on the river St. Laurence; 70 miles N.E. of Quebec.

MALEA, in *Ancient Geography*, *Capo Malio*, a town of Laconia, situated at the extremity of a chain of mountains, advancing into the sea between the Argolic and Laconic gulfs.

MALEBRANCHE, NICHOLAS, in *Biography*, a celebrated philosopher, was born at Paris in the year 1638, and instructed in the Latin and Greek languages by a domestic tutor. He afterwards prosecuted the study of philosophy at the college of de la Marche, and of divinity in the Sorbonne. At the age of 22 years, he determined to embrace a monastic life, and was admitted into the congregation of the Oratory. Weary of the researches of ecclesiastical his-

tory, to which he first directed his attention, he was advised by father Simon to apply to oriental literature and biblical criticism; but when he had acquired sufficient knowledge of the Hebrew language to read the Old Testament in the original, he desisted from the pursuit of studies of this kind; and under the influence of a temporary enthusiasm, he seemed inclined to give himself up wholly to devotion, and silently to wait for divine illumination. But he was roused from this state by the accidental perusal of Des Cartes's treatise "On Man," with the perspicuous reasoning of which he was so much pleased, that he determined to make himself thoroughly acquainted with this author's system of philosophy. With this view, he devoted ten years to profound meditation, and to metaphysical researches, which led him, under the influence of a warm and exuberant imagination, into the very visionary regions of enthusiasm. Conceiving the soul of man to be mysteriously united to his body, and apprehending also that a no less mysterious union subsisted between the human soul and God, he published, in 1673, the result of his meditations and conclusions, in his famous treatise, entitled "Recherche de la Verité," or "Search after Truth," in three volumes, 12mo. In 1676, he attempted to evince the agreement between true philosophy and religion, in a work, entitled "Christian Conversations, in which the Truth of the Religion and Morality of Jesus Christ is vindicated," 12mo. In 1680 appeared "A Treatise on Nature and on Grace," 12mo., which was the result of a controversy between him and M. Arnauld on the subject of grace; and this treatise was succeeded by several controversial tracts, written by both these authors. He published also several other pieces in vindication of his system announced in the "Search after Truth." Our author also published "A Treatise on Physical Premotion," against Bourcier's book, "On the Action of God," and "Reflections on Light and Colours, and on the Generation of Fire," and also other papers, inserted in the "Memoirs of the Academy of Sciences," of which body he was admitted an honorary member in the year 1699. By temperance he maintained a good state of health, notwithstanding the delicacy of his constitution, till near the close of life, which terminated at the age of 77 years, in 1715. His manners in private life were simple, cheerful, and complaisant. He paid little regard to those subjects of erudition which employed the thoughts and time of other literary persons; and which merely served to make them acquainted with the opinions of different philosophers, without leaving them sufficiently at leisure to think for themselves. For poetry he had no taste; and it is said, indeed, that he never read ten verses without disgust. It was his custom to study with his windows shut, that he might not be disturbed by the light. The speculations of his retirement were the subjects of his conversation, with regard to which he was communicative, and yet modest and unassuming. His company was much valued and desired; and no foreigner of learning visited Paris without wishing to be introduced to him; and we are informed by one of his biographers, that an English officer, being taken prisoner in the war between the king of France and William III., expressed his satisfaction at being sent to Paris, because he had long wished to see Lewis XIV. and father Malebranche. See the next article.

MALEBRANCHISM, the doctrine or sentiments of father Malebranche (see the last article); which is in a great measure the same with Cartesianism. It must be owned, however, that though F. Malebranche thought the same with Des Cartes, yet he does not so properly seem to have followed him, as to have met with him.

MALEBRANCHISM.

Malebranchism is chiefly contained in the "Recherche de la Verité," of which M. Fontenelle says, "The Inquiry after Truth" is full of God: God is the only agent, and that too in the strictest sense. All power of acting, all actions, belong immediately to him. Second causes are no causes. They are only occasions that determine the actions of God; or occasional causes. This work, which was first published in 1673, passed through several editions; the best of which was that published by himself in 1712, in two volumes 4to, and four volumes 12mo., with considerable variations and enlargements.

F. Malebranche, however, does not here lay down his system entire, with regard to religion, or rather the manner in which he would reconcile religion to his system of philosophy; that he reserved for his "Entretiens Chrétiens," already mentioned, where he proves the existence of a God, the corruption of human nature by original sin, and the necessity of a Mediator, and of grace.

Dr. Enfield, in his Abridgment of "Brucker's Philosophy," (vol. ii.) has given the following account of the system of Malebranche. "The doctrine of this book," referring to his 'Search after Truth,' "though in many respects original, is raised upon Cartesian principles, and is, in some particulars, Platonic. The author represents, in strong colours, the causes of error, arising from the disorders of the imagination and passions, the abuse of liberty, and an implicit confidence in the senses. He explains the action of the animal spirits, the nature of memory; the connection of the brain with other parts of the body, and their influence upon the understanding and will. On the subject of intellect, he maintains, that thought alone is essential to mind, and deduces the imperfect state of science from the imperfection of the human understanding, as well as from the inconstancy of the will in inquiring after truth. Rejecting the ancient doctrine of *species* sent forth from material objects, and denying the power of the mind to produce ideas, he ascribes their production immediately to God; and asserts, that the human mind immediately perceives God, and sees all things in him. As he derives the imperfection of the human mind from its dependence upon the body, so he places its perfection in union with God, by means of the knowledge of truth and the love of virtue."

"Singular and paradoxical as the notion of 'seeing all things in God,' and some other dogmas of this writer, must have appeared, the work was written with such elegance and splendour of diction, and its tenets were supported by such ingenious reasonings, that it obtained general applause, and procured the author a distinguished name among philosophers, and a numerous train of followers. Its popularity might, perhaps, be in part owing to the appeal which the author makes to the authority of St. Augustine, from whom he professes to have borrowed his hypothesis concerning the origin of ideas. The immediate intercourse which this doctrine supposes, between the human and the divine mind, has led some to remark a strong resemblance between the notions of Malebranche, and those of the sect called Quakers."

Dr. Reid (Essay ii.) does not allow, that either Plato or the latter Platonists, or St. Augustine, or the Mystics, thought, that we perceive the objects of sense in the divine ideas. This theory of our perceiving the objects of sense in the ideas of the Deity, he considers as the invention of Father Malebranche himself. Although St. Augustine speaks in a very high strain of God's being the light of our minds, of our being illuminated immediately by the eternal light, and uses other similar expressions; yet he seems to apply those expressions only to our illumination in moral and

divine things, and not to the perception of objects by the senses. Mr. Bayle imagines that some traces of this opinion of Malebranche are to be found in Amelius the Platonist, and even in Democritus; but his authorities seem, as Dr. Reid conceives, to be strained. Malebranche, with a very penetrating genius, entered into a more minute examination of the powers of the human mind than any one before him; and he availed himself of the previous discoveries made by Des Cartes, without servile attachment. He lays it down as a principle admitted by all philosophers, and in itself unquestionable, that we do not perceive external objects immediately, but by means of images or ideas of them present to the mind. "The things which the soul perceives," says Malebranche, "are of two kinds. They are either in the soul, or without the soul: those that are in the soul are its own thoughts, that is to say, all its different modifications. The soul has no need of ideas for perceiving these things. But with regard to things without the soul, we cannot perceive them but by means of ideas." He then proceeds to enumerate all the possible ways by which the ideas of sensible objects may be presented to the mind: either, 1st, they come from the bodies, which we perceive; or, 2dly, the soul has the power of producing them in itself; or, 3dly, they are produced by the Deity in our creation, or occasionally as there is use for them; or, 4thly, the soul has in itself virtually and eminently, as the schools speak, all the perfections which it perceives in bodies: or, 5thly, the soul is united with a Being possessed of all perfection, who has in himself the ideas of all created things. The last mode is that which he adopts, and which he endeavours to confirm by various arguments. The Deity, being always present to our minds in a more intimate manner than any other being, may, upon occasion of the impressions made on our bodies, discover to us, as far as he thinks proper, and according to fixed laws, his own ideas of the object; and thus we see all things in God, or in the divine ideas.

However visionary this system may appear on a superficial view, yet when we consider, says Dr. Reid, that he agreed with the whole tribe of philosophers in conceiving ideas to be the immediate objects of perception, and, that he found insuperable difficulties, and even absurdities, in every other hypothesis concerning them, it will not seem so wonderful that a man of very great genius should fall into this; and probably it pleased so devout a man the more, that it sets in the most striking light our dependence upon God, and his continual presence with us. He distinguished more accurately than any philosopher had done before, the objects which we perceive from the sensations in our own minds, which, by the laws of nature, always accompany the perception of the object; and in this respect, as well as in many others, he had great merit. For this, as Dr. Reid apprehends, is a key that opens the way to a right understanding, both of our external senses, and of other powers of the mind.

It is obvious, however, that the system of Malebranche leaves no evidence of the existence of a material world, from what we perceive by our senses; for the divine ideas, which are the objects immediately perceived, were the same before the world was created. Malebranche saw and owned this consequence, and therefore he rests the complete evidence which we have of the existence of matter upon the authority of revelation; by which we are assured, that God created the heavens and the earth, and that the word was made flesh. No author, not even bishop Berkeley, hath shewn more clearly, that either upon his own system, or upon the common principles of philosophers, with regard to ideas; we

have

have no evidence left, either from reason or from our senses, of the existence of a material world. It is no more than justice to Father Malebranche to acknowledge, that bishop Berkeley's arguments are to be found in him in their whole force.

Malebranchism, notwithstanding, appears to many persons not only illusive and visionary, but even dangerous, and destructive to religion; and it has accordingly been vigorously opposed by many zealous French authors. The first was M. Foucher. After him came M. Arnauld; and in 1715, F. du Tertre, a Jesuit, published an ample confutation (as he imagines) of his whole system. It was also charged with atheism by F. Hardouin, in the "Atheists Unmasked;" though his system, formed by a warm and exuberant imagination, tends more to fanaticism and enthusiasm than to atheism. That part which relates to our seeing all things in God, was answered by Mr. Locke, in a small tract printed among his posthumous works.

Those who choose to see this system, attacked on the one hand and defended on the other, with subtilty of argument and elegance of expression, and on the part of Arnauld with much wit and humour, may find satisfaction by reading Malebranche's Enquiry after Truth; Arnauld's book of True and False Ideas; Malebranche's Defence; and some subsequent replies and defences. It should be remembered, however, that Malebranche was a Jesuit, and Arnauld a Jansenist; and the antipathy between the Jesuits and Jansenists left Malebranche no room to expect quarter from his learned antagonist. Bayle justly remarks on this controversy, that the arguments of M. Arnauld against the system of Malebranche were often unanswerable, but they were capable of being retorted against his own system; and his ingenious antagonist well knew how to use this defence.

Mr. Norris, an English divine, espoused the system of Malebranche in his "Essay towards the theory of the ideal or intellectual World," published in two volumes 8vo. A.D. 1701.

MALECKH, in *Geography*; a town of the duchy of Stiria; eight miles N. of Fridaw.

MALECOTTA, a town of Hindoostan; 42 miles E. of Cochin.

MALEDICTION, **MALEDICTIO**, in *Law*, a curse usually annexed to donations of lands, &c. to churches and religious houses; imprecating the most direful punishments on those who should infringe them.

MALEENSOONOO, in *Geography*, a small island in the East Indian sea, near the S.W. coast of Palawan. N. lat. 8° 11'. E. long. 117° 22'.

MALEEPOETHAS, one of the Soloo islands, in the East Indian sea. N. lat. 6° 3'. E. long. 120° 18'.

MALEGHERY, a town of Hindoostan, in Mysore; 20 miles S. of Ouffoor.

MALEK SHAH, in *Biography*, third sultan of the Seljukian dynasty, and the most powerful prince of his time, born in 1054, was son, heir, and successor of Alp Arslan. On the death of his father he found himself placed on a throne which had the rule of Asia from the banks of the Oxus to the borders of Syria. The caliph of Bagdad conferred upon him the sacred title of commander of the faithful, which had never before been conferred on a subordinate prince. Malek had many enemies to contend with, some of whom were among his nearest relations. In 1075 one of his generals took Damascus, and reduced a great part of Syria. He invaded Egypt the following year, but was compelled to retreat by the inhabitants of Cairo. In 1078 Malek Shah undertook to complete the conquest of Tur-

kestan, which had been commenced by his father. He reduced many cities to obedience, and extended a nominal sovereignty over the Tartar kingdom of Cashgar. And by allowing his generals to conquer districts for themselves, acknowledging his paramount authority, he stretched his authority from the Chinese frontier to the mountains of Georgia, the vicinity of Constantinople, the Egyptian border, and the coasts of Arabia. His activity was so great that he is said to have visited all parts of his dominions twelve times during his reign. In these wide and extensive progresses his favourite amusement was hunting, which he pursued with vast pomp, and sometimes with a train of many thousand horsemen. In 1088 he made a pilgrimage to Mecca, in which he displayed more magnificence than any prince had done before on the same occasion. He abolished the tribute usually paid by pilgrims: he furnished them all with provisions, caused a great number of wells and reservoirs to be made in the desert, and erected places for rest and refreshment at the different stages, and he took every means of promoting the prosperity of his dominions, by the erection of public buildings, by diminishing the taxes, and by attending to the exact and rigid administration of justice. The reformation of the kalendar was one of the acts which distinguished his reign; for which purpose he assembled all the astronomers of the East to rectify the errors that had crept into the computations, and they instituted the Jalalean era, so named from Jalal, the first word of one of the sultan's titles, which era is reckoned to commence from March 15th, 1079. Much of the splendour and excellence of this reign was attributed to the illustrious vizir Nizam al Moik, who towards the close of it fell into disgrace, though very undeservedly, and who was not only deprived of his employments, but in the 93d year of his age fell by the hand of an assassin. The wound, though fatal, did not prevent him previously to his death, from writing a dignified epistle to his sovereign, asserting his fidelity, and recommending his son to the sultan. Malek, proceeding to Bagdad, with the intention, it is said, of fixing there the seat of his empire, and removing the caliph to some other place, was taken ill of a fever, which put an end to his life in 1092, in the 38th year of his age and the 21st of his reign. This prince is highly extolled for his mental and bodily qualities, and for many virtues that adorn a throne. The house of Seljuk attained its highest greatness in his person, from which it declined at his death, or rather at the death of his minister Nizam. Gibbon. Univer. Hist.

MALEL, or **MELLI**, in *Geography*, a town of Nigritia, on a river which runs into the Niger. N. lat. 13° 40'. E. long. 9° 36'.

MALELA, or **MALELES**, **JOHN**, in *Biography*, a monk of Antioch, known chiefly by a chronicle, written in the Greek language, from the creation to the reign of Justinian. It was published from a manuscript in the Bodleian library, by Edward Chilmead, of Oxford. It has been republished as a kind of appendix to the Byzantine historians at Venice, in 1733.

MALEMBO, in *Geography*, a sea-port of Africa, in the kingdom of Cacongo. It contains about 700 huts or houses, and is surrounded by a wall constructed of rough stones, without mortar. The king has a palace here in which he occasionally resides. The Dutch and Portuguese have warehouses for ivory and raw minerals, which they obtain in exchange for European goods; 15 miles S.W. of Cacongo.

MALERMI, sometimes called **MALERBI**, **NICHOLAS**, in *Biography*, a native of Venice, and by profession a monk, is entitled to a short notice, as having been the author of the first

first printed version of the scriptures into the Italian language, which was published in two volumes folio, in the year 1471, under the title of "Biblia volgare Itorata." It was reprinted in 1477, and again in 1481. He was author also of "The Lives of all the Saints," published at Venice in 1475.

MALESHERBES, CHRISTIAN-WILLIAM DE LAMOIGNON DE, born at Paris in 1721, was son of the chancellor of France, William de Lamoignon, a descendant of an illustrious family. He received his early education at the Jesuits' college, and afterwards applied himself with ardour to the study of the law, and to other subjects connected with political economy. At the age of twenty-four he was appointed a counsellor in the parliament of Paris, and in December 1750 he succeeded his father as president of the "court of aids," an important jurisdiction, the duties of which were to regulate the public taxes. The superintendance of the prefs had been conferred upon Malesherbes by his father, at the same time that he received the presidentship of the court of aids, and this function, which had usually been exercised to the suppression of all free enquiry, became in his hands the means of promoting it to a degree beyond all former example in that country. It was through his favour that the French Encyclopédie, the works of Rousseau, and the writings of other eminent men, issued from the prefs, notwithstanding the opposition and anathemas of the hierarchy. In this view of the subject, Malesherbes, as well as the philosophical party with whom he was associated, may be charged with having been materially instrumental in preparing the way for that revolution which has been the pregnant source of so many calamities. In 1771, when the tyranny of the government had proceeded to the dissolution of the whole legal constitution, and the banishment of parliaments, the court of aids participated in the general destruction, which it provoked by its remonstrances. Malesherbes was banished to his country-seat by a "lettre de cachet," and the duke de Richelieu, at the head of an armed force, abolished the tribunal. He was distinguished by his private virtues, and his time was occupied with his family and his books, and the cultivation of his grounds. His expenditure in public objects was large: he drained marshes, cut canals, constructed roads, built bridges, planted walks, and carried his attention to the comfort of the lower classes so far, as to raise sheds on the sides of the river for the shelter of the women at their domestic labours. Thus he fulfilled the part of the beneficent parent of a village, till the accession of Lewis XVI. recalled him to a public station, and in 1774 Malesherbes received an order to appear at the place where the court of aids had sat, and resume the presidentship of the restored tribunal. On this occasion he pronounced a very affecting and patriotic harangue, and afterwards addressed the king in an eloquent speech of thanks. He particularly inveighed against that spirit of despotism which had abrogated law and justice, and abolished every vestige of constitutional liberty. Such sentiments were in perfect unison with those of the young and uncorrupted king, and they procured for Malesherbes the appointment of minister of state in June 1775. This elevation was regarded by him only as affording an opportunity of extending his sphere of usefulness. One of his first concerns was to visit the prisons, and restore to liberty the innocent victims of former tyranny, and his praises were carried throughout France by persons of all descriptions returning to the bosoms of their families from the gloom of dungeons. He was desirous of abolishing the arbitrary power of issuing lettres de cachet, but not being able to effect this great reform, he procured the appointment of a commission, composed of upright and enlightened magistrates,

to which every application for such letters should be submitted, and whose unanimous decision should be requisite for their validity. Malesherbes was also a great encourager of commerce and agriculture, in which he had the cordial co-operation of the illustrious Turgot, at that period the controller of the revenue. The latter was soon dismissed from his high office by the intrigues of courtiers, and the former, owing to the rejection of some important measures, which his zeal for the public good led him to propose, resigned his post in the month of May 1776. To obtain an accurate view of the manners and policy of other countries and foreign states, he set out on his travels, and visited Switzerland and Holland, and in the course of his journey he noted down every occurrence worthy of observation, and that might, hereafter, possibly be useful to himself, and promote the melioration of his country. On his return, at the end of a few years, he found his native country so much advanced in philosophical principles, that he was encouraged to draw up and present to the king two elaborate memoirs, one on the condition of the Protestants, the other on the principles of civil liberty, and toleration in general, replete with the enlarged views of an enlightened statesman, who was at the same time a friend to the interests and happiness of mankind. Difficulties were now accumulating in the management of the government, and the king, in 1786, called Malesherbes to his councils, but without appointing him to any particular post in the administration. He soon found it impossible to act with the men already possessed of the powers of government, but he was determined, in this critical state of things, to make one effort for opening the monarch's eyes, and drew up two energetic memoirs "On the Calamities of France, and the Means of repairing them;" but such was the ascendancy which the queen's party had over the mind of the king, that he was prevented from even reading them, nor could he be prevailed upon to grant the writer one private interview; he therefore took his final leave of a court, apparently bent on its own and the nation's ruin. He retreated to his country residence, determined to consult the best means of serving his country by philosophical and agricultural pursuits, and in 1790 published "An Essay on the Means of accelerating the Progress of Rural Economy in France," in which he proposed an establishment to facilitate the national improvement in this important point. He was particularly led to make his proposal at this period, with the hope that the revolutionary changes, though so awful and sanguinary, would finally issue in a free and well balanced constitution. The dreadful scenes which very soon followed in horrible succession extinguished his hopes, and left him to mourn in solitude over the miseries of France. Every energy of his soul was, at length, roused, by the decree of the national convention for the trial of the dethroned and imprisoned king. He now seemed wholly to forget the neglect which had been offered him by the court, at a time when his advice might have essentially served it, and he felt nothing but the desire of serving the king and his family with the utmost extent of his talents. He accordingly wrote to the president of the convention, requesting the liberty of being permitted to act as one of the counsel of the fallen monarch. Three had already been appointed, but one having, from prudential motives, declined the office, Lewis, who wept at this proof of attachment from his old servant, immediately nominated Malesherbes in his stead. Their interview was extremely affecting, and Lewis, during the short interval before his death, shewed every mark of affection for, and confidence in, his generous advocate. Malesherbes was the person who announced to him his cruel doom, and was one of the last who took leave of him previously to his execution. After that

catastrophe

catastrophe he again withdrew to his retreat, and with a deeply wounded heart, refused to hear any thing of what was acting among the blood-thirsty Parisians. As he was one morning working in his garden, he observed four savage looking wretches directing their course to his house, and hastening home, he found them to be officers from the revolutionary tribunal come to arrest his daughter and her husband, who had formerly been president of the parliament of Paris. The separation of these persons from his family was deeply afflicting to his heart, and it is probable that his own arrest shortly after was a relief to his feelings. He had long been esteemed as father of the village in which he lived, and the rustic inhabitants crowded round to take leave of their ancient benefactor with tears and benedictions. Four of the municipality accompanied him to Paris, that he might not be escorted by soldiers like a criminal. He was shut up in prison with his unfortunate family: and in a few days the guillotine separated his son-in-law Lepelletier from his wife; and the accusation of Malherbes with his daughter and grand-daughter, "for a conspiracy against the liberties of the people," was followed, as a matter of course, by a sentence of death. The real crime, as it was basely denominated, of this excellent man and worthy patriot, and which the convention never pardoned, was his defence of the king, an act in which he gloried to the latest hour of his existence. He probably thought it an honour to die by the same ruffian hands that had spilt the blood of his master. The condemnation of the females almost overcame the manly fortitude which he displayed in every personal suffering; his courage, however, returned at the prison, and they prepared for the death which was the last and only important event that they had to encounter. His daughter had exhibited the noble spirit with which she was inspired, for upon taking leave of Mademoiselle Sombreuil, who had saved her father's life on the second of September, she said to her, "You have had the happiness to preserve your father, I shall have the consolation of dying with mine." On the fatal day, Malherbes left the prison with a serene countenance, and happening to stumble against a stone, he said with much pleasantry, "a Roman would have thought this an unlucky omen, and walked back again." Thus perished the venerable Malherbes in April 1794, when he had attained to his seventy-third year. He was unquestionably one of the most spotless and exemplary characters of his time. The subse-quent government has since made some reparation for the injustice done him, by ordering his bust to be placed among those of the great men who have reflected honour upon their country. Gen. Biog.

MALESHERBES, in *Geography*, a town of France, in the department of the Loiret, and chief place of a canton, in the district of Pithiviers; 10 miles N.E. of Pithiviers. The place contains 945, and the canton 6587 inhabitants, on a territory of 242½ kilometres, in 22 communes.

MALESTROIT, a town of France, in the department of Morbihan, and chief place of a canton, in the district of Ploermel; 7 miles S. of Ploermel. The place contains 1800, and the canton 11,734 inhabitants, on a territory of 255 kilometres, in two communes. N. lat. 47° 49'. W. long. 2° 18'.

MALEVANT, a small island in the English channel, near the coast of France. N. lat. 47° 22'.

MALEUS SINUS, in *Ancient Geography*, the gulf of Malea, called by the pirates who infested it the golden gulf, on account of the rich prizes which they captured here.

MALEXANDER, in *Geography*, a town of Sweden, in West Gothland; 25 miles S. of Linköping.

MALEYA, a town on the S. coast of the island of Ter-

nate, where the Dutch have a settlement. N. lat. 8° 55'. E. long. 12° 14'.

MALGARDEN, a town of Westphalia, in the bishopric of Osnabruck; 3 miles W.S.W. of Vorden.

MALGRATO, a town of Italy, in the department of the Lario; 10 miles N.E. of Como.

MALHAR, a town of Hindoostan, in Vissapour; 20 miles E. of Poonah.

MALHATTY, a town of Bootan; 60 miles N. of Dinagepour.

MALHERBE, FRANCIS DE, in *Biography*, a celebrated French poet, was born about the year 1556 at Caen, in Normandy. His father, who was an inferior law-officer, embraced the Calvinistical doctrines a short time before his death, which so much displeased the son, whose governing maxim on this point was, "That a gentleman's religion should be that of his prince," that he left his native province, and entered into the household of Henry d'Angoulême, natural son of king Henry II., and governor of Provence. Little is known of the subject of this article, till he was mentioned by Perron to Henry IV., as one who had surpassed all other composers of French poetry: two or three years after this time, viz. in 1605, Malherbe first came to court, being then about 50 years of age. The king received him into his service, and gave him a liberal salary, and after the death of the monarch he had a pension from the queen dowager. He died at Paris in 1628. He is represented as of a very unamiable temper; splenetic and sarcastic, and as having little feeling for the common charities of his kindred. He was perpetually engaged in law-suits, and his bon mots were frequently rude and severe: to a young lawyer who shewed him a poem of his own composition, he said, "Had the alternative been given you of being hanged or writing these verses, you might have been excused producing such a ridiculous piece." Dining once with the archbishop of Rouen, he fell asleep after dinner: the prelate waked him to go and hear a sermon he was to preach: "I can," said Malherbe, "sleep well enough without that." His ruling passion was that of guarding the purity of the French language, of which he exhibited a proof almost in his dying moments, when he reproved his nurse for using a word that was not of good authority: and it is farther said, that when his confessor was describing to him the happiness of a future world in mean and vulgar terms, he exclaimed, pray say no more, your style is too disgusting to be borne. With all his defects Malherbe is revered as the father of cultivated French poetry. His works consist of odes, stanzas, sonnets, epigrams, songs, and other short pieces, some of which are merely complimentary addresses to the great, and some are of a devotional cast. The best editions of his works are in 3 vols. 12mo. 1722; and in octavo 1756, edited by St. Marc. Moreri.

MALHEUREUX, in *Geography*, a small island in the gulf of Mexico, near the coast of West Florida. N. lat. 30° 6'. W. long. 89° 28'.

MALIANA, or **MANIANA**, a town of Algiers, much frequented by pilgrims, on account of the tomb of a saint, called "Sede Youseph;" 12 miles S.S.E. of Tefessad.

MALIC ACID, in *Chemistry*, is a vegetable compound, which exists ready formed in many unripe fruits; and contributes, almost exclusively, to give sourness to the apple, the barberry, the plum, and the sloe. It was discovered by Scheele in the year 1785. He has given us the following process for extracting it, in Croll's Chemical Journal for that date. Saturate the juice of unripe apples with carbonate of potash, and to the solution add acetat of lead till a turbid-

a turbidness ceases to be produced. The precipitate, which is a compound of the malic acid with oxyd of lead, must be washed in a large quantity of water, and afterwards treated with dilute sulphuric acid; fresh portions being poured on, until the mixture has lost its saturnine flavour, and become perfectly four. The malat of lead, by this treatment, will be decomposed, a sulphat being formed in its place, and the malic acid remaining free in the supernatant liquor. To separate them the fluid must be passed through a filter. Vauquelin has since ascertained, that the acid in question may be obtained from the *sempervivum tetiorum*, or common house leek, more advantageously even than from the apple. It exists in this vegetable combined with lime; and the mode of operating, which he has recommended, differs but little from the preceding, except in adding acetat of lead to the expressed juice, without the previous intervention of carbonat of potash. *Annales de Chimie*, t. 34. p. 127.

Besides the above processes for extracting malic acid, it may also be formed artificially by the action of nitric acid upon sugar. If equal quantities of nitric acid and sugar be beat together, till the mixture assumes a brown colour, two new acids will be found to have been created, having very different properties from the one originally employed. The most abundant of these is the oxalic, or that which gives sourness to the *oxalis acetosella*, or common wood sorrel, whence its name, and which will be more particularly treated of under that article. (See *OXALIC acid*.) The other is the malic; and the mode of separation employed by Scheele, who was the discoverer of this fact, is as follows: Add lime-water till a precipitate ceases to be produced; and after having filtered the liquor, present a farther quantity, sufficient to neutralize the malic acid. Alcohol must next be poured in, which will cause a coagulation to take place. The product is a malat of lime, which, when separated by the filter, and washed with fresh alcohol, must be redissolved in water. This, as before, must be decomposed by acetat of lead; and the same means resorted to, to collect the free acid.

Malic acid, obtained by any of these methods, is a brownish-red liquid of a pungent and very sour taste. It is incapable of crystallization, and presents thus a particular distinction from the other vegetable acids. When evaporated, it becomes thick and viscid; and if exposed in thin layers to an atmosphere tolerably free from moisture, it dries, forming a brilliant varnish. By heat it is easily decomposed, becoming first of a deep colour, and exhaling a thick and pungent vapour. The coaly matter which it leaves behind is very light and spongy, similar to that yielded by mucilage of sugar. The volatile products, when collected in close vessels, are, according to Fourcroy, (*Sytem* vii. 270.) an acid water, much carbonic acid, and some carburetted hydrogen. The malic acid is liable to spontaneous decomposition, when long kept in a fluid state. All the powerful acids act upon it, and change its nature. By the sulphuric it is reduced to coal, and nitric acid changes it into the oxalic; a proof of the latter containing the greatest proportion of oxygen. Malic acid unites with different bases, and forms a class of salts denominated *malats*. These have been but little examined, except by their discoverer Scheele. The malats of potash, soda, and of ammonia are very soluble and deliquescent. The neutral malat of lime exists in the form of irregular crystals, which are difficult of solution, even at a high temperature. The presence of a slight excess of acid, however, forms a super-malat, which is very readily dissolved. It is this compound which is contained in the common house leek. Malic acid, on being added to barytic

water, causes an immediate precipitation; but no such effect occurs with strontian. The latter salt, therefore, we may infer, is considerably more soluble than the former. Of its combination with the other earths, but little more is known, than that with magnesia it forms a compound which is deliquescent; while its product with alumine is very difficult of solution. It unites with some metallic oxyds; and precipitates mercury, lead, and silver from the nitrats of those metals. In this latter respect, it exhibits a striking difference from the citric acid, with which it is almost always more or less mixed in vegetables; that substance causing no change in the solutions just mentioned. (See *CITRIC acid*.) Malic acid dissolves iron and zinc; the former of which yields a brown mixture incapable of crystallization; but the latter salt may be obtained in fine regular crystals. It decomposes muriat of gold, the oxyd being reduced to the metallic state. This acid is not applied to any useful purpose.

MALICANDURGAM, in *Geography*, a town of Hindoostan, in Mysore; 19 miles N. of Allumbaddy.

MALICE, in *Ethics* and *Law*, is a formed design of doing mischief to another; it differs from hatred. In murder it is malice makes the crime; and if a man, having a malicious intent to kill another, in the execution of his malice kills a person not intended, the malice should be connected to his person, and he shall be adjudged a murderer. The words *ex malitia præcogitata* are necessary to an indictment of murder, &c. And this *malitia præcogitata*, or *malice prepense*, may be either *express* or *implied* in law. *Express* malice is, when one with a fedate, deliberate mind, and formed design, kills another; which formed design is evidenced by external circumstances, discovering that intention; as lying in wait, antecedent menaces, former grudges, and concerted schemes to do him some bodily harm. (1 Hal. P. C. 451.) Besides, where no malice is expressed, the law will imply it; as where a man wilfully poisons another; in such a deliberate act the law presumes malice, though no particular enmity can be proved. And if a man kills another suddenly, without any, or without a considerable provocation, the law implies malice; for no person, unless of an abandoned heart, would be guilty of such an act, upon a slight or no apparent cause. See **MURDER**.

MALI-CHAN, in *Geography*, a small island near the coast of China, in Quang-tong; 10 miles S.W. of Macao.

MALICHO, a town on the S. coast of the island of Mindanao. N. lat. 7° 48'. E. long. 124° 21'.

MALICIOUS MISCHIEF, in *Law*. See **MISCHIEF**.

MALICIOUS Prosecution. See **INJURY**.

MALICORNE, in *Geography*, a town of France, in the department of the Sarthe, and chief place of a canton, in the district of La Flèche; six miles N. of La Flèche. The place contains 1023, and the canton 10,226 inhabitants, on a territory of 225 kilometres, in 11 communes.

MALICOY, a low small island in the Indian ocean, between the Laccadive and Maldive islands, surrounded with breakers, and dependent on a rajah of the Malabar coast. N. lat. 8° 16' 30". E. long. 73° 9' 30".

MALICURGINAGUR, a town of Hindoostan, in Mysore; 50 miles S. of Seringapatam.

MALIDIA, a town of Africa, on the E. coast of Tunis; 110 miles S.S.E. of Tunis.

MALIGHERY, a town of Hindoostan, in Baramaul; 30 miles S.E. of Darampoory.

MALIGNANT, in *Medicine*, that quality in a disease which renders it more than ordinarily dangerous, and difficult of cure.

Malignant

Malignant is generally applied to such fevers as are epidemical or infectious, and are attended with spots and eruptions of various kinds. See *Malignant FEVER*.

MALIKERY, in *Geography*, a town of Hindoostan, in Myfore; 18 miles N. of Seringapatam.

MALIKUL, a lake of Russia. N. lat. $48^{\circ} 20'$. E. long. $60^{\circ} 14'$.

MALILLA, a town of Sweden, in the province of Smaland; 45 miles N.N.W. of Calmar.

MALINES, or MECHLIN, a city of France, and principal place of a district, in the department of the Two Nethes; lately the capital of a province of the Netherlands, comprehending a small territory with about nine towns and villages. It was the see of an archbishop, and contains six parish churches. The number of inhabitants in the town is estimated at 16,612, and in the two cantons at 24,640, in a territory of $87\frac{1}{2}$ kilometres, in nine communes. The manufactures of the place, which are considerable, are those of bed-quilts, thread, and particularly lace, which is in high estimation all over Europe. In the arsenal is a foundery for cannon, and other instruments of war. The town is distant 12 miles N. from Brussels. N. lat. $51^{\circ} 1' 50''$. E. long. $4^{\circ} 28' 45''$.

MALINHEAD, the most northern cape of Ireland, in the district of Inishowen and county of Donegal. N. lat. $55^{\circ} 23'$. W. long. $7^{\circ} 16'$.

MALINOV, an island in the mouth of the Volga, at its entrance into the Caspian sea. N. lat. $45^{\circ} 8'$.

MALISTA, one of the small Western islands, near the W. coast of Lewis. N. lat. 58° . W. long. $7^{\circ} 4'$.

MALIT, a town on the N. coast of the island of Timor. S. lat. $8^{\circ} 24'$. E. long. $125^{\circ} 55'$.

MALIVAGONGA, a large river of Ceylon, in the country of Candy, which rises at the foot of Adam's peak, a high mountain S.W. of Candy, and taking a N.E. direction, nearly surrounds the capital, and at length falls into the sea at Trincomalee.

MALIUTO, a town of Naples, in Calabria Citra; 12 miles N.W. of Bisignano.

MALKAR, a town of Hindoostan, in the country of Golconda; 54 miles W. of Hyderabad. N. lat. $17^{\circ} 17'$. E. long. $77^{\circ} 53'$.

MALKARABÆLA, in *Zoology*, the name of an East Indian species of serpent found in the island of Ceylon. It is remarkably variegated with white and dusky brown, in various figures.

MALKUITZ, in *Geography*, a town of Silesia, in the principality of Breslau; nine miles S.W. of Breslau.

MALL, or MALLET, a smaller kind of mace, a weapon used by our ancient English archers for dispatching the enemies whom they had wounded with their arrows.

MALL, or *Sea-mall*, in *Ornithology*, the English name of the *LARUS Canus*; which see.

MALLA, in *Geography*, a town of Africa, in the country of Woolly; 15 miles E. of Medina.

MALLABAUQUEN, a lake of Chili; 60 miles N.E. of Valdivia.

MALLAMA, a town of South America, in Popayan; 30 miles S.W. of Palto.

MALLANCY CHOKY, a town of Assam; 50 miles E. of Rangamatty.

MALLAPILLY, a town of Hindoostan, in Myfore; 12 miles N. of Venchatighery.

MALLARD, the *Anas Boschas*; in *Ornithology*. See DUCK.

MALLAWALLE, in *Geography*, a small island in the East Indian sea, N. of Borneo. N. lat. $7^{\circ} 2'$. E. long. $117^{\circ} 29'$.

MALLEABILITY, in *Physics*, a property principally confined to some of the metals, by which their form can be changed by the action of the hammer. When the change of figure is effected by rollers, the substance is said to be *laminable*: when by wire drawing, it is called *ductility*. The property, however, is the same in all these processes. Some bodies are malleable only at a certain temperature, such as glass, and some of the metals: others at all temperatures, to a certain degree. This is the case with most of the malleable metals.

Some bodies are not malleable till they have received a certain mechanical treatment. In such cases, it is observed, that when the body is brittle, it is under its crystalline form, or that state in which its fracture exhibits some regular figures. This is the case with iron and zinc. See METAL and ZINC.

MALLEABLE, something hard and ductile, and that may be beaten, forged, and extended under the hammer, without breaking.

All metals are malleable, not excepting even quicksilver; but gold is so in the greatest degree of all. The chemists have long sought the fixation of mercury, or to render it malleable. See MERCURY, and FREEZING.

MALLEAM, in *Geography*, a town of Hindoostan, in the Carnatic; 24 miles S.S.W. of Trichinopoly.

MALLEAMOTHE, in *Botany*, a low tree, or rather shrub, growing in Malabar. Of the roots are made hafts for knives, the leaves serve to dress the ground, and being fried in oil of palm, furnish a liniment for removing the impetigo, and drying the pustules of the small-pox. A decoction of the same, in common water, is used as a fomentation to mitigate the pains of the hæmorrhoids.

The root pulverized with ginger and saffron, and exhibited in an infusion of rice, cures the dropsy by powerfully promoting a discharge of superfluous serosities by the urinary passage. Acofta commends the shrub principally for two effects; first, against fluxes of the belly, for which purpose, however, it is of less efficacy than other medicines; secondly, for curing all kinds of erysipelas, especially such as proceed from mere bile. They macerate the whole root or trunk, bruised in a decoction of rice, and suffer them to remain there for some hours, that the water may contract an acidity; after which they anoint the erysipelas with it, and order the patient to drink a sufficient quantity of the same twice a-day, the stomach being first purged. They give the same water to those who labour under an inflammation of the liver, and the burning heat of a fever; and use it mixed with a small quantity of the juice of the leaves of tamarind, to anoint the lips of the wounds, in order to prevent an inflammation.

MALLEI EXTERNUS, in *Anatomy*, the name given by Albinus and others to a muscle of the malleus, sometimes called laxator tympani. See EAR.

MALLEI Internus, the name under which Winslow and others have described the tensor tympani muscle. See EAR.

MALLEI Superior, is the muscle described by Albinus as the laxator tympani, and by some others as the laxator tympani minor. See EAR.

MALLEMANS, CLAUDE, in *Biography*, descended from a noble family, was born at Beaune, in Burgundy,

about the year 1646. He came to Paris while he was very young, where he pursued his early studies, and, in 1664, he entered among the priests of the congregation of the Oratory, and afterwards attached himself to the university of Paris. Here he fulfilled the duties of professor of philosophy for more than thirty years with great reputation, and had the honour of giving instructions in this science to the dukes of Burgundy. He died in 1723, at the advanced age of seventy-seven, and in circumstances of distress and great poverty. He possessed a very inventive genius, and was a zealous advocate for the philosophy of Des Cartes. He invented a machine for making all sorts of dials, and was author of "A Physical Treatise on the World;" "A new System of the Load-stone;" an attempt to solve "The famous Problem of the Quadrature of the Circle;" he published many papers in the "Journaux des Sçavans," between the years 1674 and 1716. Moreri.

MALLE-MUCKE, in *Ornithology*. See FULMAR and PROCELLARIA *Glacialis*.

MALLENOWITZ, in *Geography*, a town of Moravia, in the circle of Hradisch; 10 miles N.E. of Hradisch.

MALLEOLARIS, in *Anatomy*, *malleolar*, an epithet applied to two small branches of the anterior tibial artery, distributed on the ankle joint. They are distinguished as external and internal. (See ARTERY.) The term is sometimes used in speaking of a process of the tibia, and one of the fibula. See MALLEOLUS.

MALLEOLI, among the *Romans*, bundles of any combustible matter besmeared with pitch, and used by the Roman soldiers either for giving light in the night-time, or for setting fire to some of the enemies' works.

The malleoli were sometimes fixed to a dart or javelin, that they might be sure to catch firm hold, and communicate the fire wherever they happened to light.

MALLEOLUS, in *Anatomy*, a technical term equivalent to ankle. It denotes the bony prominences, which protect the joint of the ankle. The inner and smaller of these (*malleolus internus*) is a process of the tibia; the outer and larger (*malleolus externus*) is a part of the fibula. See EXTREMITIES.

MALLEOLUS, in *Ichthyology*, a name given by Gaza and some others, to the fish called by Aristotle and the other old writers, *sphyræna*, and by the Italians *luzzo marino*.

It is a beautiful fish, and seems to belong to the scombræ, or mackerel kind. Salvian has figured it under the name of *fudis*, a name by which it is also called by Varro and some other old authors; but Salvian's figure is very imperfect; he has omitted the back-fin.

MALLEPALEAM, in *Geography*, a town of Hindoostan, in Myfore; nine miles S. of Sankeridergam.

MALLESUNDRUM, a town of Hindoostan, in Myfore; 10 miles E. of Sankeridergam.

MALLET, DAVID, in *Biography*, a poet and miscellaneous writer, a native of Scotland, was probably born in Perthshire. The name of his family was Malloch: little is known of him in early life, but in 1720 he was tutor to the children of a Mr. Home, near Edinburgh, and at the same time attended lectures in the university of that city. He had already distinguished himself by some poetical compositions, particularly by a pastoral, which brought him into notice among the Scottish literati. The treatment which he met with at Mr. Home's did not accord with his expectations, and in 1723, he gladly accepted the offer of accompanying the two younger sons of the duke of Montrose to Winchester. About this time he printed in the "Plain-

Dealer" his admired ballad of "William and Margaret;" its success induced him to resume his poetical studies, and in 1728 he published "The Excursion." About this time he changed his name from Malloch to Mallet, and in 1731 his tragedy of "Eurydice," which had been planned some years before, was brought on the stage, and was favourably received. He had now attained to a sufficient degree of consequence to be admitted to the company of men of rank and literary eminence; among these was Pope, whose ridicule of critics and commentators he echoed, in a poem published in 1733, "On Verbal Criticism." Immediately after this, the prince of Wales appointed him his secretary, with a salary of two hundred pounds a-year. In 1734, he attended the prince of Orange on a visit to Oxford, and presented to him a copy of verses written in the name of the university, on which occasion he was admitted to the degree of M.A. His tragedy of "Mustapha" was brought on the stage in the year 1739, and met with some degree of temporary success. The longest poem of this author is entitled "Amyntor and Theodora;" it is a pathetic tale in blank verse, interspersed with much poetical description, but it is generally deemed tedious. Among the prose pieces of Mallet, the most important was "The Life of Lord Bacon," prefixed to an edition of his works, which appeared in 1740; this, though an elegant and judicious article of biography, is defective in the display of what constitutes the main point of that wonderful man's merit, his character as a luminary of science. After the death of Pope, lord Bolingbroke employed Mallet to blacken his memory, in revenge for clandestinely printing his "Patriot King." In reward for this service, his lordship left him his works, which in 1754 he published in five volumes quarto, but which not only involved him in difficulties, on account of certain sentiments contained in them subversive of the principles of revealed religion, but which did not produce to the editor any profit. After this he was engaged to write the life of the great duke of Marlborough, for which he was liberally paid, with an annual pension, though it is pretty well ascertained that he never made any progress in the business. He was next employed by the ministry to attack admiral Byng, with the view, no doubt, of diverting the public odium from the real delinquents, and to throw it on the unfortunate commander. Byng was executed, and Mallet rewarded with a considerable pension. He died in 1765; he is described as a man of agreeable manners and conversation, sufficiently attentive to his own interest, but ready to serve his friends. "Nothing," says his biographer, "elevated or dignified can be discerned in his character or principles. As a poet he may lay claim to elegant diction, splendid imagery, and pathetic sentiment, but he is deficient in energy and judgment." Johnson's Lives of the Poets.

MALLET, EDME, was born at Melun in the year 1713; and in 1751 we find him engaged in serving a *cure* near his native place, when he came to Paris, and was chosen professor of theology in the college of Navarre. He made himself known by various publications, of which the following were the principal; "Principes pour la Lecture des Poètes;" "Essai sur l'Etude des Belles Lettres;" "Essai sur les Bien-seances Oratoires;" "Principe pour la Lecture des Orateurs;" "A Translation of Davila's History of the Civil Wars of France." He engaged to furnish the articles of theology, and the belles lettres for the Encyclopédie. His style in all his works is neat, clear, and unaffected. In his several treatises on poetry and polite literature, he limited himself to an accurate exposition of the precepts laid down by the best masters, illustrated by select examples. As a man and
a friend,

a friend, he was an object of esteem to all who knew him, on account of his mildness, moderation, and candour.

MALLET, JAMES ANDREW, a professor at Geneva, descended from a good family in that city, was born in 1740; he was destined for a military life, but was prevented from pursuing it by an accident in his youth, by which the muscles of his legs became contracted, and he continued lame through the whole of his life. He was educated in the public school of Geneva, and displayed an early attachment to the mathematics. From Geneva he went to Basil, and studied with great success under the celebrated David Bernouilli. In 1764 he obtained a prize from the academy of Lyons for the best answer to a mathematical prize question, and in the following year he made a tour to France and England, in the course of which he formed an acquaintance with Lalande at Paris, and the late Dr. Maskelyne, at London, and the taste which M. Mallet acquired for astronomy, was no doubt a consequence of his intimacy with these eminent men. In this science he was greatly assisted by his profound knowledge of the mathematics, in which he was continually exercising his genius and talents. He wrote two papers on the calculation of chances, which were inserted in the "Acta Helvetica;" and at the request of Lalande, he calculated a table of the aberration and nutation of the stars of the first and second magnitude, which was published in the "Connoissance des Temps," and afterwards in Lalande's great work on astronomy. On his return, he lived some time in the bosom of his family, till he was appointed by the academy of Petersburg, by the recommendation of Lalande and Bernouilli, to observe the transit of Venus in 1769, at one of the northern stations made choice of for that purpose. He was accompanied by M. J. L. Picquet, but the object of their mission was in a great measure lost by the unfavourableness of the weather. On his return, he formed an intimate acquaintance with J. A. Picquet of Geneva, who assisted him in his astronomical observations, with instruments which Mallet had procured at his own expence from England. In 1777 he was elected a member of the commission appointed to draw up a plan for settling the disputes by which the harmony of the little republic had for fifteen years been disturbed, and which were at length silenced for some time, by the intervention of foreign powers. Though Mallet was not at all ambitious of literary fame, he was honoured with unfolicited marks of distinction by several foreign societies. He was one of the members of the Academy of Sciences at Paris, and some of his best astronomical observations may be found in the memoirs of that learned society. He maintained an epistolary correspondence with the most learned astronomers in Europe; and at his country house, where he spent the greater part of his time, he employed himself in making astronomical observations, and in conversing with the neighbouring farmers on subjects of rural economy. While at Geneva, he led a retired life, but had a weekly meeting of literary friends at his house, and attended the fittings of the Society for the Encouragement of Arts. He was visited by many foreigners of distinction, and was universally esteemed for his talents, integrity, and benevolence. He died in the year 1790, of an apoplexy. Gen. Biog.

MALLET, a large kind of hammer, made of wood; much used by artificers who work with a chissel, as sculptors, masons, and stone-cutters, whose mallet is ordinarily round; and by carpenters, joiners, &c. who use it square. See HAMMER.

There are several sorts of mallets used for different purposes on ship-board. The *caulking-mallet* is chiefly employed to drive the oakum into the seams of a ship, where

the edges of the planks are joined to each other in the sides, deck, or bottom. The head of this mallet is long and cylindrical, being hooped with iron to prevent it from splitting in the exercise of caulking. There is also the *sewing-mallet*, used in sewing the rigging, by binding the spun-yarn more firmly about it than it possibly could be done by hand; which is performed in the following manner; the spun-yarn being previously rolled up in a large ball, or clue, two or three turns of it are passed about the rope, and about the body of the mallet, which, for this purpose, is furnished with a round channel in its surface, that conforms to the convexity of the rope intended to be served. The turns of the spun-yarn being strained round the mallet, so as to confine it firmly to the rope, which is extended above the deck, one man passes the ball continually about the rope, whilst the other, at the same time, winds on the spun-yarn by means of the mallet, whose handle, acting as a lever, strains every turn about the rope as firm as possible. Falconer.

MALLET, *Maule*, or *Mall*, in *Military Language*, a weapon formerly used both by the English and Scots. In the memorable combat fought in Bretagne, in the year 1315, between thirty champions on the part of the English, and the like number on that of the French, one of the English champions, named Billefert, was armed with a leaden mallet weighing twenty-five pounds. We learn also from father Daniel, that the English archers still used mallets in the time of Louis XII., who began his reign in 1515, and died in 1524. In the ancient poem of the battle of Flodden, the mention of leaden mallets often occurs; and from the following description there given of it, it seems as if the head of the mall was entirely of lead, hooped round at the ends with iron:

"Some made a mall of massy lead,
Which iron all about did bind."

Ralph Smith equips an archer with a maule of lead, five feet long, and a pike with the same, hanging by a girdle with a hook; meaning, probably, by this description, that the handle of the mall should be of this length, the end armed with a pike or spike; and this implement, we may imagine, was worn at the back, hung by a hook fixed in the centre of its handle, with a loop, or some other contrivance, to keep it nearly perpendicular. Father Daniel has engraved one of these mallets, which, in form, exactly resembles the present wooden instrument of that name, except that its handle is somewhat longer. This weapon seems to have been of French extraction; for we find, that in the reign of Charles VI., on occasion of a riot, the populace forced open the arsenal, and armed themselves chiefly with mallets, whence they were styled "Mailliotins." Mallets were tremendous weapons in the hands of strong active men, such as are described to have wielded them in the following verses:

"Two Scotch earls of an ancient race,
One Crawford called, the other Montrose,
Who led twelve thousand Scotchmen strong,
Who manfully met with their foes
With leaden malls and lances long."

"Then on the English part with speed
The bills stept forth, and bows went back;
The Moorish pikes and malls of lead
Did deal there many a dreadful thwack."

Grose's Mil. Ant. vol. i.

MALLETAR, in *Geography*, a town of Hindoostan; 60 miles E.S.E. of Cochin.

MALLEUS, in *Anatomy*, one of the small bones contained in the cavity of the tympanum. See **EAR**.

MALLI, in *Ancient Geography*, the inhabitants of the country now called *Moultan*, which see. Their capital was situated not far from the river *Rauvee* (anciently *Hydraotes*), somewhat below the present town of *Toulumba*, which is a famous pass on the *Rauvee*, between *Lahore* and *Moultan*.

MALLICOLLO, or **MANICOLA**, in *Geography*, one of the *New Hebrides*, which, to the S.E., extends N.W. and S.E., and in that direction is eighteen leagues long. Its greatest breadth, which is at the S.E. end, is eight leagues, the N.W. end is two-thirds this breadth, and nearer the middle one-third; a contraction which is occasioned by a wide and pretty deep bay on the S.W. side. Captain *Cook* represents it as fertile and well inhabited: the land on the sea-coast is rather low, and lies with a gentle slope from the hills which are in the middle of the island. The inhabitants, forming what *Cook* denominates an ape-like nation, are described as the most ugly ill-proportioned people he ever saw, and different from any met with in this sea. They are a very dark-coloured and diminutive race; with long heads, flat faces, and monkey countenances. Their hair, mostly black or brown, is short and curly; but not quite so soft and woolly as that of a negro. Their beards are very strong, crisp, and bushy, and generally black and short. But what most adds to their deformity is a belt, or cord, which they wear round their waist, and tie so tight over the belly, that the shape of their bodies is not unlike that of an overgrown pismire. The men go quite naked, except a piece of cloth, or leaf, used as a wrapper. Few women were seen, but they were not less ugly than the men; their heads, faces, and shoulders are painted red; they wear a kind of petticoat; and some of them had something over their shoulders like a bag, in which they carry their children. Their ornaments are ear-rings made of tortoise-shell, and bracelets, wrought with thread or cord, and studded with shells, worn just above the elbow. Round the right wrist they wear hogs' tusks, bent circular, and rings made of shells, and round their left a round piece of wood, designed probably to ward off the bow-string. The bridge of the nose is pierced, in which they wear a piece of white stone, about 1½ inch long, and of a curved form. As signs of friendship, they present a green branch, and sprinkle water with the hand over the head. Their weapons are clubs and spears, made of hard and iron-wood, and bows and arrows. The bows are four feet long, made of a stick split down the middle, and partly circular; the arrows are a sort of reeds, sometimes armed with a long sharp point of bone, and the points were covered with a substance found to be poison. Their arrows they carefully preserve in a quiver; and some of them are armed with two or three points, each with small prickles on the edges, to prevent the arrow from being drawn out of the wound. Their language is different from that of any other nation: the letter *R* often occurs in their words; and they express their admiration by hissing like a goose. Their houses are like those of the other isles, low, and covered with palm thatch. Their fruits, such as the bread-fruit, plantains, and cocoa-nut trees, are not so good as those of the *Society* or *Friendly Isles*; but their yams appeared to be very good. Their animals are pigs and fowl; they have not so much as a name for a dog, and consequently they have none. Pieces of cloth, and marbled paper, were articles which they most esteemed; but edge tools, nails, and beads, they seemed to disregard.

The harbour, visited by captain *Cook*, is situated on the N.E. side of *Malicollo*, not far from the S.E., and in S. lat. 16° 25' 20". E. long. 167° 57' 23", and was called by

him *Port Sandwich*. It lies in S.W. by S. about one league, and is one-third of a league broad. A reef of rocks extends out a little way from each point; but the channel is of a good breadth, and has in it from forty to twenty-four fathoms of water. In the port the depth of water is from twenty to four fathoms; and it is so sheltered, that no winds can disturb a ship at anchor there. Another great advantage is, that you can lie so near the shore, as to cover your people, who may be at work upon it. Two reddish fish, resembling a large bream, and of the same size, were caught in the harbour, which appeared, by their effects on those who partook of them, to be poisonous. This sort of fish is mentioned by *Quiros* under the name of *pargos*. *Cook's Second Voyage*, vol. ii. See *NEW HEBRIDES*.

MALLING, **WEST**, or *Town Malling*, a market-town and parish in the hundred of *Larkfield*, lathe of *Aylesford*, and county of *Kent*, England, is situated six miles distant from *Maidstone*, and thirty from *London*. The manor was given, says *Lambard*, "to *Burbius*, bishop of *Rochester*, by king *Edmund*, the brother of *Athelstane*, under the name of *Three Plough-lands* in *Mealings*." After a temporary alienation, it was restored to the bishops of this see, previously to the *Domefday Survey*, at which time "here were a church and a mill." In the year 1090, bishop *Gundulph* founded a *Benedictine* nunnery here, and endowed it with the manor, church, and other estates: he governed it in person during his life, but directed that in future it should be under the jurisdiction of an abbot, subordinate to the bishops of *Rochester*. In 1190, the abbey, as it was then called, and the village, suffered by fire, but were soon restored: in the time of king *John*, the abbots had a grant of free-warren for all her demesne; and *Henry III.* added the privilege of a weekly market, and three annual fairs. After the dissolution, the manor and abbey-buildings were exchanged with archbishop *Cranmer*, and have since passed through various families to the *Honeywoods*. The late *Filmer Honeywood*, esq. pulled down the abbey-house, and with the materials erected the present mansion, preserving, as much as possible, the ancient style and form. It is now the residence of *George Talbot Hatley Foote*, esq. Many parts of the conventual pile are, however, yet standing, being used as offices, together with a portion of the west end of the abbey-church, which is an interesting remain of Norman architecture, and is ornamented with sculptures of heads, animals, and intersecting arches. The abbey grounds are watered by a clear stream, which flows from *Nether-Well*, in the hamlet of *St. Leonard's*; where is yet standing the ruined tower of *St. Leonard's chapel*, a very strong remain, much resembling the keep of a Norman castle: its present height is seventy-one feet; the walls are seven feet in thickness.

The town of *West Malling* consists principally of one spacious street, well built, and about half a mile in length, together with several detached mansions belonging to respectable families. The parish-church is a large fabric, consisting of a nave and chancel, with a Norman tower: the nave has been mostly rebuilt since the year 1778, when the whole roof fell in, through the decay of the main columns. Here are some ancient and curious brasses. A small free-school was built in 1632, by a bequest of *Mr. Francis Trefle*. The population return in the year 1801, stated the inhabitants of *West Malling* to be 1093, occupying 192 houses.

In *East Malling*, a village about a mile distant, is *Bradbourne*, the seat of *Mr. John Papillon Twyden*, bart., which, though not particularly extensive, forms one of the most delightful residences in *Kent*. Some good portraits of the learned

learned judge Twyfsden, who died here in 1666, are preserved in Bradbourne-house. Hasted's History and Topographical Survey of Kent, twelve vols. 8vo. Beauties of England and Wales, vol. vii.

MALLOCOCCA, in *Botany*, so called by Forster and in the Upsal Transactions, is a species of GREWIA. See that article.

MALLOTUS, according to Loureiro, was so named from *μαλλωτος*, hairy, the capsule of this plant being profusely and remarkably beset with hairs. Loureir. Cochinch. v. 2. 635.—Class and order, *Diazia Polyandria*. Nat. Ord. *Tricoccea*, Linn. *Euphorbia*, Juss.

Gen. Ch. Male, *Cal.* Perianth inferior, of three roundish, concave, woolly leaves. *Cor.* none. *Stam.* Filaments numerous, short, inserted into the receptacle; anthers two-lobed, roundish.—Female, *Cal.* Perianth of three triangular, equilateral, hairy, expanded leaves. *Cor.* none. *Pist.* Germen superior, roundish, three-lobed; style none; stigmas three, oblong, hairy, coloured, reflexed. *Peric.* Capsule roundish, of three lobes, six valves, and three cells, single-seeded, covered with a multiplicity of long and soft hairs. *Seeds* roundish on one side, angular on the other, remaining on their proper stalks upon the receptacle, after the capsule has fallen away.

Eff. Ch. Male, Calyx of three leaves. Corolla none. Stamens numerous.—Female, Calyx of three leaves, inferior. Corolla none. Stigmas three. Capsule three-celled. Seeds solitary, stalked.

Obs. Loureiro remarks, that this genus is nearly related to *Cliffortia*, but that it differs in having the capsule superior and three-celled, as well as in having three fertile stigmas.

1. *M. Cochinchinensis*. Cày. Bèt. of the natives. Loureir.—Found about hedges and neglected gardens, in Cochinchina and China.—The only species known.—This tree is of middling height, with spreading branches. Leaves alternate, roundish, generally three-lobed, a few however are undivided, ovate, pointed, all of them stand on footstalks, are toothed and downy. Flowers reflexed, in loose clusters, ending in a spike.

Loureiro found the Male Flowers of *Mallotus* occasionally to vary, in having their calyx-leaves lanceolate, hairy, and spreading. Filaments upwards of forty, shorter than the calyx; anthers ovate, erect.—He met with this variety growing near Canton, but could find no female flowers in that neighbourhood.

MALLOW, in *Botany*, &c. See MALVA.

MALLOW, *Bastard*. See MALOPE.

MALLOW, *Jews'*. See CORCHORUS.

MALLOW, *Indian*, See URENA.

MALLOW, *Indian*, or *Yellow*. See SIDA.

MALLOW, *Rose*. See ALCEA.

MALLOW, *Sea*, *Malva marina*, in *Natural History*, a name not very judiciously given by some writers to a species of submarine substance, supposed in some degree to resemble the leaves of the common mallow. It is very common in the places where they fish for coral, and grows to the rocks without any regular root; it is found at different depths, but most usually far from the surface, and its height is usually about two inches; it is of a dusky greenish colour, with an admixture of faint yellow; it is composed of several leaves about half an inch broad, and a little more than that in length: each of these is fastened to a pedicle of about an inch and a half long; the leaves are of a fine thin membranaceous substance, but their stalks or pedicles are thick and rough like horn. When examined by the microscope many glandules discover themselves upon the surfaces of the leaves,

but the stalks or pedicles are entirely covered with glandules in form of small protuberances, which make it as rough in those parts as the common shagreen. The stalks when cut transversely shew an infinite number of pipes or vessels running up to every part of the leaves. Count Marfigli has given an elegant figure of this, both as it appears to the naked eye, and by the microscope.

MALLOW, *Syrian*, in *Botany*. See HIBISCUS.

MALLOW, *Tree*, *varied-leaved*, or *Venetian*. See LAVATERA.

MALLOW, *Vervain*, a species of the *malva*, or common mallow. Some have called the *alcea* by this name.

MALLOW, *Yellow*. See SIDA.

MALLOW, in *Geography*, a post-town of the county of Cork, Ireland, situated on the river Blackwater, over which it has a stone bridge. It is much frequented on account of a soft and tepid spring (discovered in 1724), of the same nature and efficacy as the Hot-wells of Bristol. Mallow was incorporated in 1688, and is governed by a provost and burgesse; and it sends a member to parliament. It is 117 miles S.W. from Dublin, and 15 N. by W. from Cork. A tract of country on each side of the river constitutes the liberties of Mallow, and is inhabited by several respectable families.

MALM, in *Agriculture*, a term sometimes applied to a sort of white marley clay. It is a substance that has been found beneficial on soils of the stiff clayey kind when laid on in pretty large proportions, as about sixty tons per acre. In one instance of this kind of soil, mentioned in the fourth volume of Communications to the Board of Agriculture, when applied in this proportion on a very large scale, the produce was full three times as great per acre, as in the original state. It is asserted that the quality of this substance may be best proved by common vinegar; in which case a portion should be dried, and put into a wine glass full of vinegar; when, if it instantly begins to effervesce and attract the acid, it may be depended on to be highly useful as a manure. It may be used in other cases also with great benefit.

MALMEDY, in *Geography*, a town of France, and principal place of a district, in the department of the Ourte; 23 miles E.S.E. of Liege. The place contains 4344, and the canton 12,007 inhabitants, on a territory of 232½ kilometres, in six communes. This town has some mineral springs, which are reckoned equal, if not superior, to those of Spa. Its principal manufacturers are employed in making cloth and dressing of cotton. The town was taken by the French in October, 1794. N. lat. 51° 24'. E. long. 6° 7'.

MALMESBURY, a borough, market-town, and parish in the northern part of Wiltshire, England, is a place of note in the monastic annals of the country, and still retains some interesting remains of its ancient splendour. Its early history is involved in doubt, and is so blended with the romances of monachism and superstition, that it is difficult to separate the facts from the fables of old chronicles. Leland states that a castle was built here four or five centuries before the Christian era. Other writers say that Dunwallo-malmutius, king of the Britons, gave it the appellation of Caer Bladon, and that it was afterwards successively denominated Ingleburne, Maildulfburgh, Aldelmsbirig, and Meildunum.

The history of this town is intimately connected with the history of its religious establishments. A convent of British nuns, under the direction of Dinoh, is said to have been settled here towards the close of the sixth century, but its inhabitants being accused of living in a state of incontinency with

with the soldiers in the castle, it was suppressed by Augustin, the first archbishop of Canterbury. About this time Medolph, a Scot, remarkable for his piety and strict holiness of life, who had left his own country on account of persecution, fixed his residence here, and established a school for his support. Having collected a number of persons disposed to embrace a monastic life, he built a small monastery, which was shortly afterwards received under episcopal jurisdiction. The town, at this period, seems to have been a place of considerable importance, but no records in its secular history are extant prior to the year 878, when it appears to have been attacked and burned by the Danes. It afterwards suffered again by fire in the reign of Edward the Elder, who constituted it a borough by charter, so that it is amongst the most ancient corporations in the kingdom. In the time of his successor Athelstan, two battles appear to have been fought in this neighbourhood, with the piratical invaders, already mentioned, in which the men of Malmesbury displayed great valour, and in consequence received a confirmation of their charter, with additional privileges. The place was subsequently the theatre of the contest, which king Stephen had to maintain against his turbulent barons, as well as against his competitor Henry of Anjou. The latter prince having laid siege to, and took it in a very short time, together with the castle, except one tower, which finding too strong to be taken by assault, he blocked it up with the view of reducing it by famine, and notwithstanding the vigorous attempts of Stephen to produce its relief, ultimately effected his object. After this period nothing worthy of notice occurs in the history of Malmesbury, till the era of the civil wars in the reign of Charles I. when it was several times besieged and taken both by the republicans and royalists.

This town is built on a commanding eminence, peninsulated by two streams which unite to form the lower Avon. According to the parliamentary returns of 1801, it then contained 207 houses, and 1027 inhabitants, of whom 83 were returned as employed in different branches of trade, but this must be erroneous. In former times it was much more extensive than at present, many of the streets described in old records being totally demolished. The principal manufacture carried on here is that of woollen cloth, for which it was famous at an early period, but a number of hands are employed in the leather trade, and in the manufacture of gloves, parchments, glue, &c. There is a weekly market on Saturdays, and one also on the last Tuesday of each month, called the great market. Besides the churches belonging to the establishment, there are four places of public worship appropriated to the meetings of dissenters. The only charitable institutions are two alms-houses, and two free schools.

It has been already mentioned that the original charter to this town was granted by Edward the Elder, and confirmed by his successor Athelstan. Charters of confirmation, with additional privileges, were likewise bestowed by several succeeding monarchs. The present one is dated in the reign of William III. and by virtue of it the government is vested in an alderman, a high steward, twelve capital burgesses, and twenty-four assistants. The alderman and high steward, or their deputies, are justices of the peace.

The other persons connected with the borough are styled landholders and commoners. In the latter charters the commoners are denominated free-burgesses, and constitute the lowest members of the corporation. The landholders occupy a situation between them and the assistant burgesses, and are entitled by their office to the possession of an acre of land for life. Two members have been sent by this borough to

parliament, from the third year of the reign of Edward I. During the last century it was celebrated for its electioneering contests, the higher branches of the corporation claiming the exclusive privilege of voting at elections, while the lower members maintained their title to participate in the nomination of their representatives. The point, however, was finally decided by a committee of the house of commons in the year 1796, in favour of the alderman and twelve capital burgesses, who will, therefore, probably enjoy their privileges henceforth without opposition.

Malmesbury abounds with remains of antiquity, which sufficiently declare its former greatness. The most extensive and important of these is the abbey. By the donations and grants, both of princes and private individuals, this institution soon rose into great celebrity. The church was built in the form of a cross, and the whole buildings are said to have covered no less than forty-five acres of ground, including the garden and offices belonging to the monks. The church was a noble structure of great extent, and surmounted by two magnificent towers, one of which stood in the middle of the transept, and the other at the west end. This, as well as every other portion of the monastery, was built at different times, at least underwent such alterations and repairs as, no doubt, changed materially the original edifice. The western front is said by Brown Willis to have been an uncommonly fine piece of architecture, and richly adorned with sculpture. Over the entrance, on this side, was a very magnificent window filled with painted glass. About a fourth of the building only now remains. Both the towers are long ago levelled with the ground, that at the west end having been battered down during the civil wars, when, it is probable, the cloisters also were demolished, as no trace of them can be discovered above ground. Part of a mosaic pavement, however, was found a few years ago, in a garden to the north-west of the church which is supposed to have formed the floor of that portion of the monastery. The southern porch of this church is a truly curious and interesting specimen of ancient architecture. It consists of two distinct divisions; an exterior arch, or coved recess, with a series of archivolt mouldings, charged with a great variety of sculptured figures in basso-relievo; within this is a square apartment, or vestibule, on each side of which are large statues in basso-relievo, and over the door is another compartment, said to be meant to represent the Deity on a throne, supported by angels, and just within it is a head, supposed to represent our Saviour crowned with thorns. In the interior, the nave is divided from the side aisles by round columns, with plain capitals, above which are three rows of arches. The groins in the vaulting are adorned with foliage and heads. On this altar-piece are carved griffins, dragons, and other grotesque figures. At the north-east of the church stands a building, denominated the abbot's house, the lower part of which is a remnant of that edifice.

A particular history and description of the abbey church, with several plates, illustrative of its architecture, have been published in the first volume of Britton's "Architectural Antiquities of Great Britain."

The remains of the old parish church of St. Paul stands on the southern side of the cemetery, and opposite, on the same side, is the old vicarage house. The building called Chapel-house, on the western side of the town, is supposed to have constituted the chapel of the ancient nunnery, already mentioned. The White-lion inn, and the alms-house, together with the workhouse, and some other buildings, present remnants of more ancient structure, in general dedicated to religious purposes, or connected with monastic establishments.

As to the castle, erected by Roger, bishop of Sarum, as some suppose on the site of an older one, no traces of it can now be discovered with any certainty; but there is a well, still called the Castle-well, which probably belonged to it. In the market place stands a very beautiful market cross of stone, of an octangular shape, and much enriched with a variety of sculpture. About a mile south from the town lies a field, called "Cam's Hills," in which are two enclosures, one of them perfectly square, and the other of an oblong shape, both of which are usually esteemed vestiges of a Roman encampment.

Malmesbury no less claims the attention of the biographer than of the antiquary, some of the greatest luminaries of remote and modern times having been born here. Among the more ancient worthies may be reckoned Meydulph, Aldhelm, Johannes Scotus, and Roger le Poer, all of them men distinguished for their piety and learning. William of Malmesbury is one of the most celebrated historians this country can boast of; and Thomas Hobbs, whatever prejudice may reply to the assertion, was undoubtedly a philosopher of great acuteness. He it was who laid the foundation of that moral and metaphysical system, the illustration and development of which have bestowed immortality on the names of Hartley, Hume, and Priestley. Moffatt's History, &c. of Malmesbury, 8vo. 1805.

MALMIGNATTO, in *Natural History*, a name given by the inhabitants of the island of Corsica to a species of animal, or large insect, called by some *tarantula*, and ignorantly supposed to be the same with the tarantula of Apulia. (See TARANTULA.) This island produces neither wolves, serpents, nor many other of the mischievous and destructive animals which infest the neighbouring countries: but it produces two species of this venomous insect, called the *malmignatto*; the one of these has a round body, and the other an oblong one, resembling that of our large kind of ant; it has also six legs, not eight, and never makes any web: from all which it appears not to be a spider, but truly of the ant kind, though a monstrous sized one, and very venomous. The round-bodied kind, by its bite, occasions violent pains, a sensation of coldness and cramps all over the body; and the long-bodied one is yet more venomous. Its sting occasions an immediate lividness of the flesh, with intolerable cramps and convulsions over the whole body; sometimes the natural evacuations by stool and urine are also wholly stopped by it. The cure, in both cases, is to be attempted by cutting and cauterizing the wound, and dressing it with Venice treacle, as also by giving the same in large doses dissolved in wine.

MALMISCH, in *Geography*, a town of Russia, in the government of Viatka, on the Viatka; 100 miles S. of Viatka. N. lat. $56^{\circ} 44'$. E. long. $50^{\circ} 14'$.

MALMO, a small island on the W. side of the gulf of Bothnia. N. lat. $63^{\circ} 13'$. E. long. $18^{\circ} 40'$.

MALMOE, a sea-port town of Sweden, reckoned by some writers the capital of Scania or Schonen, situated on the Sound. This town is surrounded with walls, moats, and bastions, and is defended by several fortifications and a castle towards the sea. Here are two burgo-masters, a good school, one Swedish and one German church, an orphan-house, a large market-place, fine regular streets, and several woollen manufactures; nine miles S.W. of Lund. N. lat. $55^{\circ} 36' 37''$. E. long. $13^{\circ} 1' 4''$.

MALMSÅS, a town of Sweden, in Sudermanland; 23 miles W.N.W. of Nyköping.

MALMSEY, or MALVASY, a rich luscious kind of wine brought from Greece or Candia; so called from Mal-

vasia, a city in Peloponnesus, the ancient Epidaurus, whence this celebrated liquor was first brought.

That brought from Candia is now esteemed the best.

MALMSEY, or *Malvisy*, is also the name of a kind of muscadine wine brought from Provence.

MALNAIR, in *Geography*, a town of Hindoostan, in the province of Sirhind; 40 miles S.W. of Sirhind. N. lat. $30^{\circ} 26'$. E. long. $75^{\circ} 25'$.

MALNOS, a town of Hindoostan, in the circle of Sirhind; 20 miles W.S.W. of Sirhind.

MALO, a town of Italy, in the Vicentin; 11 miles W. of Vicenza.—Also, a town of Africa, in the kingdom of Fonia.

MALO, or *Maloës, St.* a sea-port town of France, and principal place of a district, in the department of the Ille and Vilaine, situated on a small island joined to the continent by a mole, at the head of which is a strong fort. Before the revolution, it was the see of a bishop suffragan of Tours, who was lord of the town. The harbour is large, and much frequented, though difficult of access on account of the rocks which surround it. It is strong by its situation on a peninsula, connected with the land by a narrow mole about six or seven hundred yards in length, and by the defence of 250 pieces of cannon mounted on its ramparts. But as it has no outworks, its fortifications could not long resist a regular siege: its strength both by nature and art lies towards the sea. Several attempts have been made against it, at different times, but without success. It has always been a port for privateers, and on this account has been injurious to the trade of England. N. lat. $48^{\circ} 39' 3''$. W. long. $2^{\circ} 1' 26''$.

MALO-de-la-Lande, *St.*, a town of France, in the department of the Channel, and chief place of a canton, in the district of Coutances. The place contains 449, and the canton 10,252 inhabitants, on a territory of 140 kilometres, in 13 communes.

MALOBATHRUM, among the Romans, a precious kind of ointment, brought from the Indies through Syria to Rome.

MALOGOCZ, in *Geography*, a town of Austrian Poland, in the palatinate of Sandomirz; 60 miles W. of Sandomirz. N. lat. $50^{\circ} 4'$. E. long. $20^{\circ} 18'$.

MALOGRANATUM. See POMEGRANATE.

MALOIAROSLAVETZ, in *Geography*, a town of Russia, in the government of Kaluga; 32 miles N. of Kaluga. N. lat. 55° . E. long. $36^{\circ} 14'$.

MALOKETSKOI, a town of Russia, in the government of Tobolsk; 30 miles S.W. of Kamikoi.

MALONG, a town of Hindoostan, in the Carnatic; 18 miles S. of Madura.

MALOOD, a town of Hindoostan, in the circle of Cicacole; 16 miles N.E. of Ganjam.

MALOPE, in *Botany*, is thought by professor Martyn to be a corruption of *μολαχην*, à *mallow*.—Lian. Gen. 355. Schreb. 467. Willd. Sp. Pl. v. 3. 799. Mart. Mill. Dict. v. 3. Juss. 272. Cavan. Diss. 2. 84. Desfont. Atlant. v. 2. 120. Lamarck Illustr. t. 583. (Malacoides, Tournef. t. 25.)—Class and order, *Monadelphia Polyandria*. Nat. Ord. *Columnifera*, Linn. *Malvacea*, Juss.

Gen. Ch. Cal. Perianth inferior, double; outer of three, heart-shaped, acute, permanent leaves; inner of one leaf, more erect, permanent. Cor. Petals five; inversely heart-shaped, abrupt, affixed at the base to the tube of the stamens. Stam. Filaments numerous, united below into a tube, separate and loose above; anthers nearly kidney-shaped. Pist. Germens superior, roundish; style simple, the length

of the stamens; stigmas many, simple, bristle-shaped. *Pericarpium*. Capsules roundish, of many cells, equal in number to the stigmas, forming a little head. *Seeds* solitary, kidney-shaped.

Ess. Ch. Calyx double, the outer one of three leaves. Capsules irregularly heaped together, single-seeded.

1. *M. malacoides*. Linn. Sp. Pl. 974. Cavan. Diff. t. 27. f. 1.—Leaves oblong, obtuse, undivided, notched, smooth above. Stalks solitary, axillary.—A native of meadows in Tuscany and Algiers.—*Root* annual. *Stem* erect, hairy, rough. *Leaves* somewhat heart-shaped; the lower ones obtuse; the upper generally three-lobed. *Flowers* rose-coloured; the petals wedge-shaped, truncated. *Fruit* collected into a head, like the blackberry.—The whole plant has greatly the appearance of a mallow, especially in the shape and colour of its flowers. Desfontaines notices a variety of this, whose leaves and corolla are twice the usual size.

2. *M. parviflora*. Mart. Mill. Dict. L'Herit. Stirp. Nov. fasc. 5. 105. t. 50.—Calyx simple. Leaves almost heart-shaped, even. Peduncles scarcely longer than the petiole. A native of Peru, where it was discovered by Dombey.—*Root* annual. *Stem* about a foot high, much branched, red, villose. *Leaves* alternate, on footstalks, nerved, bright green. *Flowers* axillary, on stalks, solitary, occasionally two together, purple.—Professor Martyn observes that “there are other Peruvian species with a simple calyx, which might therefore constitute a distinct genus.”

3. *M. multiflora*. Willd. n. 2. Cavan. Diff. 2. 85.—Leaves roundish, undivided, notched, villose. Stalks three or four together, axillary.—A native of Spain.—Cavanilles describes it thus. “*Stem* about six inches high, not much branched. *Flowers* small and white. *Fruit* proportionably larger than in the other species.”

4. *M. trifida*. Willd. n. 3. Cavan. Diff. t. 27. f. 2.—Leaves oblong, three-lobed, pointed, toothed, smooth. Stalks solitary, axillary.—Found in meadows both in Spain and Barbary.—Willdenow says it differs from the last in having its leaves three-lobed, more acute, and thicker.

MALOPE, in *Gardening*, contains a plant of the herbaceous kind, of which the species cultivated is, the betony-leaved malope (*M. malacoides*.)

Method of Culture.—This plant may be increased by sowing the seeds, in the places where the plants are designed to remain, as it does not bear transplanting well; when they are sown upon a warm border in August, the plants also frequently stand through the winter, and flower early the following season, so as to produce good seeds; but when sown in the spring, this is rarely the case.

It is mostly necessary that the plants sown in the spring in pots should be protected in winter under a frame. They seldom continue longer than two or three years at most, as good plants.

All of them afford variety among other plants in the borders, clumps, &c. of ornamented grounds.

MALOPINGOVSKOI, in *Geography*, a town of Russia, in the province of Usting; 108 miles N. of Usting.

MALORN, a small island in the N. part of the gulf of Finland. N. lat. 65° 32'. E. long. 23° 27'.

MALO-RUSSIANS, the denomination of those people who inhabit the country between the Dnieper and the Donetsk, called in the maps Little Russia. They are described by Dr. Clarke (*Travels in Russia*) as a race much superior to the Russians; being not only of a better aspect, but more industrious, more courageous, more cleanly, and more polite. With regard to their cleanliness, a traveller might fancy him-

self transported from Russia to Holland. In their features, the Malo-Russians resemble the Cossacks; and the similitude which both bear to the Poles, seems to imply a descent from a common origin. In one point, however, *viz.* the love of liquor, the Malo-Russians are unfortunately as gross delinquents as their neighbours to the eastward.

MALORY, a town of Hindoostan, in Myfore; 13 miles N.E. of Ouffoor.

MALOSCHANY, a town of Russia, in the government of Pskov; 24 miles N.E. of Pskov.

MALOUCA, a town of Syria, which has two churches; 20 miles N.N.E. of Damascus.

MALOUR, a town of Hindoostan, in Baramaul; 13 miles N. of Namacul.

MALOWITZ, a town of Bohemia, in the circle of Koniggratz; seven miles E. of Gittchin.

MALOWPOUR, a town of Hindoostan, in Oude; 48 miles W. of Lucknow.

MAL-PADDY, a town of Hindoostan, in Myfore; 11 miles W. of Tripatore.

MALPARTIDA, a small town of Spain, in the province of Eitramadura, containing a population of about 1300 inhabitants. It is tolerably well built; and has a handsome parish church, built with granite, supplied from an adjacent quarry; about three miles from Placentia.

MALPAS, a mountain of France, through which the Languedoc canal passes.

MALPAS, a market town and parish in the hundred of Broxton, and county palatine of Chester, England. It is situated on a lofty eminence at a short distance from the river Dee. The name of this place is supposed to have been derived from the term *Mala-platea*, illustrative of the steep, narrow, and intricate road by which it was anciently approached. The manor was one of the baronies granted, at the time of the conquest, to Hugh Lupus, earl of Chester, from whom the present noble family of Cholmondeley is descended. The magnificent castle by which it was adorned for several centuries, is now so entirely demolished, that scarcely a vestige of it can be discovered. Three streets, tolerably well built and paved, form the chief part of the town, which, according to the parliamentary returns of 1801, contained 191 houses, and 906 inhabitants. In the church is a vault, appropriated as the burying place of the earls of Cholmondeley, who derive their title of viscount from this town. The living is a rectory, and being very valuable, is divided into two portions, supporting two rectors, and the like number of curates. Malpas has a free-grammar-school and alms-house, both of which were founded by sir Randle Brereton. Adjoining the town is Cholmondeley Hall, the magnificent mansion of earl Cholmondeley, a modern building, seated on a pleasant, and somewhat elevated site. The ancient structure, though venerable in appearance, and moated round, was a very disagreeable residence, from being placed in a low and marshy situation. Lysons's *Magna Britannia*, vol. ii. 4to.

MALPICA, a town of Portugal, in the province of Beira; 16 miles S.S.E. of Castel Branco.

MALPICO, a town of Spain, in Galicia, on the sea-coast; 20 miles W. of Corunna.

MALPIEV, a town of Spain, in New Castile; 25 miles W. of Toledo.

MALPIGHI, MARCELLO, in *Biography*, a celebrated Italian naturalist, was born at Crevalcuore, near Bologna, in 1628. Having devoted himself to the study of medicine, which he selected for his profession by the advice of Natalis, his tutor in philosophy, he began to apply himself to ana-

MALPIGHI.

tomy with great zeal under Maffari, who had a school for dissection in his own house. He soon became distinguished by the philosophical spirit of observation with which he pursued his enquiries, and his ardent zeal for natural knowledge was accompanied with singular modesty. His merit procured him, in 1653, the degree of doctor in medicine, and the appointment of professor of physic, in the university of Bologna, in 1656: soon after which he was invited to Pisa by the grand duke of Tuscany, Ferdinand II. This prince, partly from his own hereditary taste, and partly at the instigation of his accomplished brother, the cardinal Leopold de Medici, was very desirous of encouraging the arts and sciences in his dominions. Here he formed a friendship with the celebrated Borelli, to whose communications he acknowledges himself indebted for the discovery of the futility of the philosophy of the schools, and of the necessity of experiment as the sole foundation of a true philosophy. The air of Pisa, however, did not agree with Malpighi, whose health was always delicate, and he was obliged to return to Bologna in 1659, where he was immediately re-appointed to the professorship of medicine. Here he resumed his inquiries with great diligence, and was the first who employed the microscope in examining the circulation of the blood. In 1662, on the death of Castelli at Messina, Malpighi was invited by the magistracy to succeed him as professor of medicine in that school, with a large salary. He occupied this post almost four years with considerable reputation; but as he paid little respect to the doctrines of the Galenists and Arabians, and excited much jealousy in his colleagues, he became involved in controversies, which rendered his life very uneasy. He therefore resolved to return to Bologna in 1666, and accepted the offers of his countrymen to continue among them, notwithstanding the pressing invitations which he received from Messina to resume his chair in that city. His anatomical pursuits now occupied a great portion of his time, at a villa, in the vicinity of Bologna; and his reputation extended throughout Europe, as a philosophical inquirer; so that, in 1669, he was elected a member of the Royal Society of London; which body afterwards testified their regard for him by printing his works at its own expence. At Bologna, he continued to teach others, and to instruct himself, with great reputation, till the year 1691. Cardinal Pignatelli, who had known him, during his own residence as legate at Bologna, being that year raised to the papacy, by the name of Innocent XII. chose Malpighi for his chief physician and chamberlain. The latter of course gave up his academical appointments, and removed to Rome, where, having previously suffered from gout and nephritic complaints, he died of an apoplexy at the palace of Monte Cavallo, November 29th, 1694, in the 67th year of his age. His remains were embalmed, and conveyed to Bologna, where they were interred with great funeral honours in the church of St. Gregory, and a statue was erected to his memory. He was married to the sister of his preceptor Maffari; but left no issue. Malpighi is described as a man of a serious and melancholy temperament, which is confirmed by his portrait in the meeting-room of the Royal Society at Somerset house. He was indefatigable in the pursuit of knowledge, on the sure ground of experience and observation, ever candid in his acknowledgments to those who had given him any information, and devoid of all ostentation or pretension on the score of his own merits. He ranks very high among the philosophers of the physiological age in which he lived, the age of Harvey, of Redi, of Rudbeck, and of Bartholin, when nature began to be studied instead of books, and the dreams of the schools gave place to practical enquiries and observations. Hence arose the discoveries of the

circulation of the blood, the absorbent system of the animal body, and the true theory of generation. To such improvements the investigations of Malpighi, relative to the anatomy and transformation of insects, particularly the silk-worm, and the development of the chick in the egg, lent no small aid. From these enquiries he was led to the anatomy and physiology of plants, in which he is altogether an original, as well as a very profound, observer. His line of study was the same as that of Grew, but these philosophers laboured independent of each other, and their frequent coincidence evinces the accuracy of both. See GREW.

The first work which he published in 1661, and which was afterwards frequently reprinted, comprised his microscopical observations relative to the intimate structure of the lungs, and was entitled "Observationes Anatomicæ de Pulmonibus," fol. He published separate tracts concerning the brain, the tongue, the external organ of touch, the omentum, throat, and the adipose ducts, between the years 1661 and 1665; and subsequently, other tracts respecting the structure of the viscera, the kidneys, spleen, liver, membranes of the brain, &c.

Malpighi became a fellow of our Royal Society, as we have already mentioned, in 1669, in which year his essay "*de formatione pulli in ovo*" was first printed, at London, in quarto, as well as his remarks on the "*Bombyx*" or silk-worm, and "*De Glandulis conglobatis*," forming his three "*Dissertationes Epitolicæ*." His "*Anatome Plantarum*," addressed to the Royal Society, accompanied by observations on the incubation of the egg, was published by that learned body in folio, with many plates, in 1675 and 1679. His works were republished at London in 1686, making two folio volumes; and more correctly at Amsterdam, in 1687, 4to. and a posthumous volume appeared here, accompanied with an account of his life, in 1697, of which a re-impression was given at Venice, and another at Leyden, the ensuing year. Some other dissertations are to be found in the "*Bibliotheca Anatomica*," published by Le Clerc and Marget at Geneva in 1685; especially "*De Cornuum Vegetatione*," "*De Utero et Viviparorum Avis*;" and "*Epistolæ quædam circa illam de ovo dissertationem*." His only medical work, "*Consultationum Medicinalium Centuria prima*," was edited by Gaspari, in 1713, 4to. Patau. He is not, indeed, distinguished as a practitioner, but he deserves praise for pointing out the mischiefs of blood-letting, in the malignant epidemics prevalent in Italy in his time. An edition of the whole of his works was printed at Venice, in 1733, in folio, by Gavinelli.

The merits of Malpighi as a vegetable anatomist are of the highest and most original kind. The structure and component parts of plants had been little attended to before he entered upon his enquiries. His illustrations of their anatomy, as well as of their external configuration, even of such of their diseases as arise from the attacks of insects, whence the various kinds of galls are formed, (see GALLS,) are all no less faithful than original. As a vegetable physiologist, too, he doubtless advanced very far; and that subject being so entirely new when he and Grew entered upon it, nothing could be more unjust than to complain of the errors into which they have fallen. The principal of these, however, requires to be mentioned. They both conceived the woody fibres of plants to transmit the sap, though no perforation could be discovered in them. If this hypothesis now excite our wonder, we must recollect that no less a philosopher than Du Hamel adopted, and laboured with all his might to support, the same opinion. Grew went a step nearer the truth than Malpighi, when he observed that they both took for *tracheæ*, or air-vessels, to be sometimes filled with sap; but

he did not hence correct his original idea, of those spiral-coated vessels being the lungs of plants, nor were they, till very lately, known to be the real sap-vessels, or arteries of the vegetable frame. (See CIRCULATION of Sap, GREW, and DU HAMEL.) Malpighi Opera. Hall. Bibl. Bot. Dryandr. Bibl. Banks. Dict. Eloy Dict. Hist. de la Méd.

MALPIGHIA, in *Botany*, was named by Plumier in commemoration of the scientific attainments of Marcello Malpighi, professor of medicine at Bologna, the celebrated vegetable anatomist; see the last article. Plum. Nov. Gen. 46. t. 36. Linn. Gen. 227. Schreb. 306 and 803. Willd. Sp. Pl. v. 2. 731. Mart. Mill. Dict. v. 3. Ait. Hort. Kew. ed. 2. v. 3. 102. Juss. 253. Cavan. Diff. 8. 405. Lamarek Illustr. t. 381.—Class and order, *Decandria Trigynia*. Nat. Ord. *Tribilata*, Linn. *Malpighia*, Juss.

Gen. Ch. Cal. Perianth inferior, of one leaf, deeply five-cleft, erect, very small, permanent, converging; with two honey-bearing, oval, gibbous glands, adhering to three, four, or to all the segments, on the outside at the bottom. Cor. Petals five, orbicular, large, plaited, fringed, spreading, concave; with long, linear claws. Stam. Filaments ten, awl-shaped, short, erect, forming a cylinder, combined at the base; anthers ovate, or rather heart-shaped. Pist. Germen superior, ovate; styles three, two, or only one, short; stigmas globose. Peric. Drupa globose, torulose, large, one-celled. Seeds three or two, bony, oblong, obtuse, angular, single-celled; occasionally solitary, globose, and three-celled. Kernels oblong, obtuse.

Eff. Ch. Calyx of one leaf, very deeply five-cleft, with two honey-bearing pores at the base of the segments externally. Petals five, roundish, with claws. Filaments cohering at the base. Drupa of one cell, with three seeds.

Obs. Most authors have described the calyx of *Malpighia* as composed of five leaves, but it is rather to be considered as of one leaf only, very deeply cleft.—We find nine species in Linnæus, thirteen in the new edition of *Hortus Kewensis*, and twenty in Willdenow, from which we select the following as sufficiently illustrative of the genus. Many of them are beautifully figured in Jacquin's works.

M. glabra. Smooth-leaved Barbadoes Cherry. Linn. Sp. Pl. 609. Curt. Mag. t. 813.—Leaves ovate, entire, smooth. Peduncles umbellated.—A native of the West India islands, where it is cultivated for the sake of its acid pulpy fruit, in size and shape somewhat resembling our cherries. Jacquin says that the fruit is usually made into a preserve with sugar, but that he has eaten it in a crude state without suffering any inconvenience. This tree flowers in the winter and spring, and grows to the height of sixteen or eighteen feet, seldom however exceeding ten feet in this country. Trunk erect, delicately branched. Leaves opposite, nearly sessile. Flowers in terminal, axillary clusters, of a beautiful pink colour, and sweetly-scented, somewhat like a jasmine.

M. polytachia. Many-spiked Barbadoes Cherry. Ait. Hort. Kew. ed. 2. v. 3. 103. Andr. Repos. t. 604.—Leaves entire, oblong, smooth, shining, with two glands at the base underneath. Clusters axillary. Flower-stalks with one gland.—A native of Trinidad, and one of those splendid plants sent over by lord Scaforth when he was governor of Barbadoes. It flowered in the stove of A. B. Lambert, esq. at Boyton, in Wiltshire, in the month of April, whence Andrews's figure was taken.—A *sub us* of free growth. Branches twiggy, covered with a brownish bark. Leaves opposite, large and handsome, on silky bristly stalks. Flowers in a spiked cluster, yellow, appearing in November, but not expanding till the spring.

M. glandulifera. Quadriglandular Malpighia. Ait. Hort. Kew. ed. 2. v. 3. 103. Jacq. Ic. Rar. v. 3. t. 469.—Leaves elliptic-ovate, acute, undulated, downy, with four glands at the base underneath. Clusters axillary on uniglandular stalks.—A native of woods in the Caraccas, flowering in our stoves about July or August, but never bearing fruit.—This shrub is about twelve feet high, branched. Leaves opposite, on short footstalks, from three to five inches long. Clusters axillary, solitary. Petals yellow, crisped at their edges. with furrowed claws and roundish borders.

M. urens. Stinging Barbadoes Cherry, or Cowhage Cherry. Linn. Sp. Pl. 609. Cavan. Diff. 8. t. 236. f. 1. (*Mespilus americana*; Tournef. Inst. 642.)—Leaves oblong-ovate, with rigid, decumbent bristles underneath. Stalks single-flowered, aggregate.—Native of South America, flowering from July to October.—Stem about three feet high, covered with a brownish bark, much branched. Leaves acutely pointed, sessile, very finely clothed beneath with depressed needle-like bristles. Flowers of a light purple colour, on long, slender stalks, four, five, or six together in a sort of whorl. Seed not perfected in England.

M. crassifolia. Thick-leaved Barbadoes Cherry. Linn. Sp. Pl. 610. Brown. Jam. 231. Aubl. Guian. t. 182.—Leaves obovate, acute, entire, downy beneath. Clusters terminal.—Found in the West India islands, and at Guiana.—The trunk of this tree is sixteen feet or more in height, branched at the summit. Leaves opposite, thick, somewhat rigid, smooth and green above, downy and rusty-coloured beneath. Flowers in a long, terminal, clustered spike, yellow. Among the Caribbees this plant is called *Mourcila*.

M. volubilis. Twining Barbadoes Cherry. Ait. Hort. Kew. ed. 2. v. 3. 105. Sims in Curt. Mag. t. 809.—Branches twining. Leaves oval, acute, shining. Clusters corymbose, terminal.—A native of the West Indies, flowering in our stoves during the Autumn.—Stem shrubby. Bark beset with warty excrescences, of an extremely small size. Leaves opposite, drooping, on weak, flattish footstalks. Flowers chiefly terminal, yellow, of very short duration.—“This shrub (says Dr. Sims) is known in our nurseries by the name of *Hirza reclinata*, but does not at all correspond with the character of that plant in Jacquin's *Historia Stirpium Americanarum*.”

M. coccigera. Linn. Sp. Pl. 611. Jacq. Ic. Rar. t. 470.—Leaves subovate, toothed, or spinous.—Found also in the West Indies.—Stem two or three feet high, branched. Leaves lucid, cut off apparently at the ends, thorny. Flowers lateral, on single-flowered stalks, pale bluish-coloured.

Professor Martyn has added five species from Jacquin, which are unnoticed by other authors, though perhaps comprehended by them. These are called *marimicensis*, *diphylla*, *odorata*, *grandifolia*, and *altissima*.—Jacquin says also that the fruits of several species of *Malpighia* are gathered promiscuously and eaten in the West Indies. They have a pleasant acid flavour, which is always grateful to the inhabitants of hot climates. *M. glabra* however is most esteemed on this account.—This genus is well deserving of attention from cultivators possessed of stoves or hot-houses, because many of its species retain their leaves all the year, and continue flowering from December to March, when there is the greatest scarcity of other flowers.

MALPIGHIA, in *Gardening*, comprehends plants of the exotic, evergreen, shrubby kind for the stove, of which the species cultivated are, the smooth-leaved Barbadoes cherry (*M. glabra*); the pomegranate-leaved Barbadoes cherry (*M. puniceifolia*); the stinging Barbadoes cherry (*M. urens*); the narrow-leaved Barbadoes cherry (*M. angustifolia*); the shining-leaved Barbadoes cherry (*M. nitida*);

da); the thick-leaved Barbadoes cherry (*M. crassifolia*); the mullein-leaved Barbadoes cherry (*M. verbascifolia*); and the scarlet grain-bearing Barbadoes cherry (*M. coccigera*).

Method of Culture.—All these sorts of plants may be increased by sowing the seeds in the spring in pots of light rich earth, and plunging them in a hot-bed. When the plants have attained a few inches in growth they should be planted out into separate small pots, re-plunging them in a bark hot-bed in the stove; where they should remain the two first winters, being afterwards placed in a dry stove, and kept in a moderate warmth, water being occasionally given in small quantities at a time.

They all afford ornament among collections of plants of similar kinds in hot-houses.

MALPIGHIE, in *Botany*, so called from the principal genus among them, a natural order of plants, the 67th in Jussieu's system, or seventh of his thirteenth class. For the characters of this class, see *GERANIA* and *GUTTIFERÆ*. The *Malpighiæ* are thus defined.

Calyx in five deep divisions, permanent. *Petals* five, alternate with the calyx, furnished with claws, and inserted into a glandular disk placed under the germen. *Stamens* ten, inserted into the same disk, five of them opposite to the petals, the five alternate ones opposite to the segments of the calyx; the filaments are sometimes united at their base, anthers roundish. *Germen* either simple or three-lobed; styles three; stigmas three or six. *Fruit* either consisting of three capules, or of three cells, the capules or cells single-seeded. *Cocculum* destitute of albumen, with a straight radicle, the lobes reflexed at their base. The plants are either small trees or shrubs. *Leaves* opposite, simple, with more or less appearance of stipulas. *Flower-stalks* sometimes terminal, more frequently axillary, either single-flowered and several together, or solitary and many-flowered, the flowers either somewhat umbellate, or spiked, or paniced, their partial stalks being, for the most part, jointed in the middle, and furnished there with a pair of small scales.

The first section, with a three-lobed germen, and a fruit of three capules, contains *Banisteria* and *Triopteris*.

The second section, with a simple germen and fruit, consists of *Malpighia* alone; see the preceding article.

A third section, of genera allied to the above, comprises *Trigonion* of Aublet, and *Erythronium* of Browne and Linnæus.

Cavanilles refers the genera of this order to the class *Monadelphica* of Linnæus, on account of a slight, and by no means universal, combination of the bases of their filaments; or rather perhaps from the insertion of those parts into one common annular disk or receptacle. This appears to us to be not only forcing nature, but to lead to much inconvenience in practice. It is the error of those who, undertaking the study or explanation of any particular tribe, or family, of natural productions, are ever desirous of augmenting it by all possible means, and perhaps, with prejudiced eyes, see almost every thing as appertaining to their favourite subject.

MALPLAQUET, in *Geography*, a village of Hainaut, famous for a battle fought there Sept. 11, 1709, between the allies under the command of the duke of Marlborough and prince Eugene, and the French under marshals Villers and Boufflers. Victory was valiantly and obstinately contested; till at length the field of battle was abandoned to the confederates, who lost on this occasion 20,000 of their best troops, whereas the vanquished enemy did not lose half the number; 8 miles S.E. of Mons.

MALPOLON, in *Zoology*, the name of a species of serpent found in the island of Ceylon, and beautifully variegated with red marks in the form of stars.

MALSARA, in *Hindoo Mythology*, a manifestation of the goddess Parvati to accompany her lord Siva, in his avatara, or incarnation, under the name and form of *Kandeb Rao*, which see. She and her lord are very popular deities in the country of the Mahrattas, where, at the elegant temple of Jejuri, they are propitiated by numerous pilgrims. (See *JEJURY*.) It does not, however, appear that the tales related of this avatara are extensively known, or that they are to be found in any very ancient books.

MALSCH, in *Geography*, a town of the duchy of Baden; ten miles E. of Spire.

MALSESENA, a town of Italy, in the Veronese; 18 miles N.N.W. of Verona.

MALSKAR, two small islands in the gulf of Bothnia. N. lat. 61° 55'. E. long. 21° 7'.—Also, a small island on the E. side of the gulf of Bothnia. N. lat. 61° 55'. E. long. 21° 7'.

MALT, in *Agriculture*, a name applied to barley, after it has undergone the process of malting; as by this means it becomes fit for making ale, beer, or other similar liquors.

It is said, that the soil on which barley grows makes a considerable difference in the grain, and that the barley fittest for malt is that which grows on a rich, light, or gravelly soil, and which has been raised from seed brought from a farm of a different soil and situation. The fullest and largest grained parts of such crops should be chosen for making malt. It should be heavy, and perfectly sound, and such as has not suffered any accident in the field. Its being a very little heated in the mow is by some considered rather an advantage, as the grain will be more equally dried, and will consequently the more equally imbibe water; but when it has been so much hurt in the mow as to look blackish when broken at the thick end, it is unfit to make good malt. It is also found by experience, that barley taken immediately from the field does not malt so kindly as that which has been some time in the house or mow. And particular care should be taken that it is free from the seeds of weeds; for these in the malting are apt to give the grain a bad taste, which cannot afterwards be got rid of.

It is noticed that in the process of germination, all the principles of the grain are put in action. The heat which it undergoes separates and divides its parts; and the viscidness which it before possessed, is removed or converted into a sweet principle, or sugar.

But in order to its being malted, the barley is put into a cistern lined with lead or stone, and covered with water about six inches deep above the barley, to give room for its swelling. All the good grains sink in the water, but after stirring it, the imperfect or distempered ones rise to the surface. These should be skimmed off, and given to poultry or hogs, for they will never make good malt. By the water's gaining admittance into the barley, a great quantity of the air is expelled, as appears from the number of bubbles which rise on the surface.

It is usual for the barley to be left in the water two or three days, more or less, in proportion to the heat of the weather and the dryness of the grain. A judgment is formed that grain is fully saturated with water, from its appearing turgid, and easily giving way to an iron rod, dropped perpendicularly into it. Or, by taking a corn from the middle of the cistern, and holding it steadily, by the two ends, between the fore-finger and thumb; pressing it gently, and if it continues firm when so pressed, and the skin does not break, it must soak longer; but if it crushes together and feels mellow, and the skin crack, it is watered enough. Nicety in this is a material point, and can be learnt only by experience. If the grain should be suffered to remain too

long in the water, it would begin to lose part of its sweetness. When it has been steeped sufficiently, the water is drawn off.

And the water used for this purpose should be that of a clear running stream, or rain-water; or if such cannot be had, pond-water, provided it be sweet and clean, will do very well; or pump-water, which should be rendered soft, if it be naturally hard. If the water made use of is any way tainted, it communicates to the malt a taste which it never loses.

When taken from the cistern, the barley is laid in a regular heap, where it must remain thirty hours, or till it contracts a heat. It must then be worked in one or more heaps, and turned every four, six, or eight hours, according to the temperature of the air; and as it *comes*, as its sprouting is commonly termed, the heap must be spread thinner to cool it, lest it be heated too much, and the germination be carried on too fast. The turning of it must be continued in proportion as it is more or less slow in growth, so that it may be brought tolerably dry to the skin. When the spires begin to deaden, the couch must be thickened again, and often turned, that the growth of the sprout may not revive. At this time the spire should be near piercing through the outer skin of the barley; as if it grows quite out, the strength of the malt will be too much consumed. After the malt is made thus far, the common practice is to lay it at once on the kiln: but the best way is to gather it all up in one heap, to let it lie in that state for twelve hours, and then to turn it every fourth hour during the space of twenty-four hours. No person should be suffered to tread on the malt with their shoes while it is on the floor, because many grains are inevitably bruised thereby, and these, vegetating no longer, afford the roots of the other grains a substance into which they extend their fibres, and are by that means entangled in bunches: and besides this, the bruised corn acquires a degree of putrefaction which taints the liquor made from the malt. Equal care should also be taken, that the grain be not bruised by any other means.

According to some, the time most proper for malting is, when the temperature of the air is such, that the grain naturally begins to germinate. How far the limits may be extended, experience alone can determine. The warmer the weather is, the greater must be the disadvantage under which the maltster labours; because the motion of the fluids is then so strong, that the process goes on too quick, and the finer parts are apt to fly off, the consequence of which is, that instead of a sweet, the malt inclines to a bitter taste. This is so universally experienced, that brewers carefully avoid purchasing what is termed latter made malt.

The grain thus prepared for drying is spread on the kiln, where, meeting with a heat greater than is suited to vegetation, its farther growth is stopped. It is spread on the kiln three or four inches thick, and turned every three or four hours. The laying of it thicker is attended with inconveniences, among which is particularly its being unequally dried; and therefore that should be avoided. The strength and duration of the fire are different, according as the malt is intended to be dried pale, amber, or brown. The pale malt requires more leisure, and less fire, than the amber or brown. Pale and amber malt are dried with coke or culm, which not emitting any smoke, give it a brighter colour, and do not communicate that bad flavour which it has when dried with wood, straw, &c. Coke is best, as it affords a steady and constant heat, whereby the malt is dried more uniformly. Where wood, or any vegetable fuel is used, it should be extremely well dried, in order that, being as free as possible from moisture, it may yield less smoke.

An ingenious and attentive maltster found the degree of heat in the malt whilst on the floor to be, during the first ten days, between fifty and sixty degrees. During the next three or four days, from sixty to sixty-five, and seventy-seven degrees; and during the last days of its being there eighty, eighty-four, and eighty-seven; which last was the degree of heat when the malt was put on the kiln. There cannot be any absolute rule as to the difference of heat during the different times in the process of malting, because it must be suited to the heat of the air; at least we have not yet sufficient data whereon to found such a calculation. The heat of the malt on the kiln, when fit for pale malt, was 120 degrees, and when it was fit for brown malt, 147.

The observation, that malt is fit for what is called pale, when its heat is 120 degrees, suggests a caution which should be carefully attended to, namely, that whatever colour it be intended to give the malt, the heat at first should be the same: thus, for example, malt which is dried to the degree of high brown, should first be rendered pale malt, then amber, and so on progressively; not by a sudden increase of the fire, but by a longer continuance of it. In this manner the whole body of the grain is equally and gradually dried; whereas a strong and quicker fire would parch, or as it were, singe the outside, while the internal parts remained moist; and as that moisture is afterwards evaporated, it must crack the surrounding hardened crust, and damage the grain in another respect.

As soon as the malt is dry, it must be removed from the kiln, and spread thin, that it may cool to the temperature of the air. It cannot be supposed that any of its parts are capable of retaining the heat in such a manner as not to suffer it to escape, though some have conceived that to be the case. In proportion as malts are dried, their particles are more or less separated, and coming in contact with water, they strongly attract from it particles which fill up their interstices. In mashing, this action between the malt and the water generates a small degree of heat, but not durable; though from hence arose the opinion, that brown malt is full of fire or heat.

It should be stated that the size of the malt-kiln should be proportioned to the quantity of malt for which it is intended. Some build their kilns square, and others make them round; but this last is undoubtedly the best form, as the heat of the fire is more equally diffused therein, and the grain is of course more equally dried. Various substances have been made use of for covering the kiln, such as tiles, plates of tin, and wire: of these the wire is to be preferred, because it does not contract so great a degree of heat as to parch the grain in contact with it; but for this very reason, hair-cloth is probably preferable to any other covering; as when any part of the malt is in immediate contact with a substance much more solid than itself, and therefore capable of receiving a proportionably greater degree of heat, the malt in contact with that heated body is parched or burnt, by the heat which is not equally diffused through the whole mass; which mass cannot, therefore, be all equally heated. The hair-cloth is spread upon small wooden rafters, and these are supported by bars of iron laid across the kiln. See KILN.

There can be little doubt that the grain may, at a medium, be said to lose by malting one-fourth of its weight, including what is separated from it by the spires screened off; but this proportion varies according as it is more or less dried. The condition of the barley, as to its greenness or ripeness, at the time of its being gathered in, is clearly discernible when it is malted. If it was gathered green, it rather loses than gains in quantity; the malt becomes

comes

comes of a smaller body, appears shrivelled, and often is unkindly hard; whilst, on the contrary, that which was cut at full maturity increases in malting, appears plump, bright, and clear, if properly carried through the process, and on being cracked, readily yields that fine mealy substance so much desired by the brewers.

Malt which has not had a sufficient time to shoot, so that its plume, or *acrospire*, as the adepts in malting call it, may have reached the inward skin of the barley, remains charged with too large a quantity of its unattenuated matter. All those parts which have not been put in motion by the act of germination being, when laid on the kiln to dry, so hardened as not to be readily soluble in water, and consequently will be lost to the strength of the liquor. When it is suffered to grow too much, or until the spire has shot through the skin of the barley; though all that is left be malt, yet, as too large a portion of its essential part will have been expended in vegetation, the malt must be greatly diminished in proportion to what it ought to have been, and what remains cannot be so fit for brewing drink for long keeping. And such as has been duly worked on the floor will, if it has not been sufficiently dried on the kiln, be apt to germinate or sprout afresh, perhaps take on a very great heat; and should it continue long with a moderate degree of heat, the least evil that can be expected is, that it will grow mouldy and have an ill flavour. When it has been well worked, but over dried, it will be so hardened, that it will not imbibe from the air that moisture which is necessary to mellow it, and render it fit for brewing; for when it has been previously softened by the moisture of the air, it mixes more easily and more intimately with the water, and by that means yields a more copious extract than it would otherwise do. Such malt as has just, or but lately been taken from the kiln, remains warm a considerable time. Until it becomes as cool as the surrounding air, it does not mellow by the addition of a due quantity of moisture from the air; and the wort made of such malt requires a much longer boiling before it breaks, than that which is made of malt some months old.

The practice of sprinkling water upon malt newly taken from the kiln, to give it the appearance of having been made a proper time, or to plump it, is highly prejudicial, as tending not only to defraud, as less grain fills the bushel, but if not used speedily, heats, soon grows mouldy, and suffers great damage.

It is obvious, that malt dried on a kiln not sufficiently heated must require a proportionably longer time for it to receive the due effect of the fire; for want of which it will be in the same state as that not thoroughly dried. Or if the fire be too quick, or too fierce, instead of gently evaporating the water from the corn, it scorches the outward skin, and separates it from the body of the grain. The malt to which this happens is called brown malt, and is very bulky; and if such a fire be continued, it changes some parts of the grain into so brittle a substance, that the malt is said to be glassy. The particles which are thus hardened will not dissolve, or but in small proportion; so that they frequently occasion an almost total want of extract, which, in the phrase of the art, is termed the setting the *grist*.

It is suggested that the goodness of malt may be known by the following marks: when a grain of it is broken, and it tastes mellow and sweet, breaks soft, and is full of flour from one end to the other, it is good. If it has a round full body, and upon putting some grains into water, they swim on the surface, it is good. Barley sinks in water, and

malt that is not well made will do the same: but it is to be observed that this is not an invariable proof, because, if the malt be broken, or in the least cracked, it will take in water, and sink. Malt that is rightly made will not be hard, but of so mellow a nature, that if drawn over an oak board, across the grain, it will leave a white line upon the board, like a mark of chalk. Its smell also may be consulted; for malt, though otherwise good, may have contracted an ill scent from the fuel, or from the water used in the steeping.

In respect to the changing the water in steeping, some maltsters think it no wise necessary; others, on the contrary, approve of it, but do it indiscriminately in the same proportion during the whole season. They are probably in both respects wrong; for the times when the water requires to be changed oftenest, are the beginning and latter end of the season, in autumn and spring, when the weather is warm; for in the middle of the winter the weather is too cold to admit of the water being at all changed to any advantage. Suppose the barley to be left in steep forty-eight hours in the spring; if the weather is inclinable to be warm, the water may in that space of time be changed three times; in other cases twice may be enough: but the best rule is, as it is well known, that in the autumn and spring, if barley is left too long on the steep in the same water, the water will grow slimy, and sometimes sour: the maltster should watch the changes of the water, and when he finds that it is smooth and oily to the touch, and that it is inclinable either to smell or taste sour, let him by all means have it instantly changed; but he must observe, if he regards his interest, a particular method even in doing this. The usual way of changing the water is, first to draw off that in which the barley was steeping, and afterwards, by pails full, or by pumping, fill the cistern again. But it is advised, as a better method, to have some water in readiness to pour on immediately after the first is withdrawn, as by that means the danger of heating is prevented. Much mischief often arises from the not changing the water at these seasons.

In converting this substance to the purpose of brewing, it should be freed from the tails and dust before it is ground, which would otherwise heighten the colour of the wort, render the liquor muddy, and give it a bad taste, which cannot afterwards be got rid of. A cylindrical sieve will be useful for this purpose.

In grinding, when too small, its flour will mix too freely with the water, and cause the wort to run thick. Many are of opinion that the best way is only to crack it, so that none of the grains may come out whole; for the intent is, that the water should draw out an extract, but not be mixed with the mealy part, in the manner of a paste or gruel. Some think that malt is better ground by a stone-mill than by a steel one, because the former bruises it, and the latter only cuts the grains.

After it is ground it should lie some time to mellow in a cool room, where no sun comes. The time for this is different, according to its kind. Brown malt may be ground as from three to four or five days before it is used, in order that the corn, which is rendered uncommonly hard by the degree of drying, may be gradually softened by the moisture of the air; by which means it will become the more soluble in water. The pale malts require only one or two days. After lying thus in the air, less mashing suffices; the strength of the malt is more perfectly extracted, and the beer will be considerably stronger than it would be with the same quantity of malt taken directly from the kiln; but care must be taken that it get no damage

damage in lying. Further experiments on these points, however, are wanting to render them satisfactory. See BREWING.

In addition to what has been stated above, on the drying of malt, an experienced maltster remarks, that his constant practice has been to give his malt as much drying as he could on the floor; this is not only a great saving of fuel, but also attended with several other advantages. The malt, by being thus gradually divested of its outward moisture, does not shrink so much when it comes to be laid on the kiln; and of course it measures to more advantage, and is besides of a better quality, having acquired no foreign taste. It is supposed that where malt is laid very damp on the kiln, a thick smoky vapour immediately arises from the surface of it, which, being repelled and condensed by the cold circumambient air, falls again on the malt, where, by the heat from the furnace, it is a second time rarefied, and ascends in clouds of steam; and that this alternate rarefaction and condensation of the moisture is of great difficulty to the malt, by often giving it a disagreeable musty flavour, and making it more unfit for keeping. But by the method of suffering the malt to receive a part of its drying on the floor, this inconvenience is, it is believed, in a great measure avoided; as the gross moisture is evaporated before it is laid on the kiln, and that which remains creates no great degree of steam, provided the fire in the furnace is not at first made to burn too fierce. The above maltster states that with this precaution he has often made pale malt as fine as he has seen any where, such as was constantly praised. In drying it, he took care that there was, during the whole time it was on the kiln, but a very moderate, yet equal, fire in the furnace.

It is suggested in the fifth volume of the Farmer's Magazine, that the best *pale malt*, for making beer, is only capable of being produced by drying it with steam; and that such grain as is intended to be malted, should have its dampness corrected, and be rendered fit for keeping only by the heat of steam, as it is known that exposure to a naked fire, however cautiously managed, destroys a great part, if not the whole, of the embryo germs of seeds.

In order to have malt highly dried, as some like brown malt better than pale, when the moisture was nearly evaporated, the above-mentioned maltster caused the fire to be gradually increased till it roared in the furnace, taking care that the malt should be properly stirred, lest it proved kiln-burnt; and by this method he had a fine, sweet, brown malt, fit for making harvest beer, such as some farmers are very fond of brewing.

It is the opinion of some, that brown malt, used in the same proportion with pale, will make the strongest beer; but this is certainly a mistake, as the above maltster has often made the experiment with great precision, but could never find any material difference, and what difference there was at any time, seemed to him to be rather in favour of the pale than the brown malt: this may easily be accounted for, as the flour in the pale malt always remained found and uninjured in the drying; while the brown malt sometimes, notwithstanding all the care of the maltster, is liable to be injured or parched by the fire, and that part must, of course, lose much of its virtue. It is, however, noticed, that such pale malts as are slack dried make a raw, unwholesome liquor, which will not keep well, but if pale malt be gradually and slowly dried by an uniform gentle heat, it will certainly answer the character he has given of it, and besides, keep as well as any brown malt whatever, as he has fully experienced.

It is stated, that in the spring and autumn, the making

of malt in all its branches is a very critical business; as it is then particularly necessary that the beds, or couches, should be frequently turned, or the malt will not come kindly: as the first root will be apt to shoot forth vigorously, starving the other roots, and preventing them from accompanying it in its growth: this must be checked, and the remedy is, to turn the couch often, spread it thin, and give it a sufficient quantity of air, at the same time keeping it cool and temperate. This will stop the progress of the first root, give the others time to sprout, and the barley will then malt kindly and more regularly.

A thin-skinned fine-coated barley is said to be best for making malt, and it is not worse for not being very full-bodied; but a lean, half-starved, unripe grain should not by any means be recommended. And such as has grown on lands highly manured is not so good for making malt as that which has been produced on land of a moderate richness without it. In fact, a luxuriant soil, whether naturally so or enriched by art, is not, in general, best for yielding barley for the maltster's use. Some prefer, for malting, a grain which is the produce of a soil that is rather poor than rich, rather light than strong, and more inclined to a gravel than a clay; as this grain is clean-coated, taper, and elegant in its form, is full of flour, mostly transparent when watered, and will be sufficiently wetted in forty-eight hours. It also increases in the malting, fills the bushel well, and makes a fine, sweet, wholesome, clean, full-bodied malt, from which the best beer may be brewed, either brown or pale, according as the malt has been dried higher or lower.

Mixed grain, or such as is grown on various soils, and in different situations, should never be purchased when it can be avoided, as it will be apt to disappoint the buyer, from the kernels springing at different times, and some of them not at all; so that after the couch is dried, some part of it will only be half malted, and a great deal not malted at all.

The following method is recommended to discover malt that has been made of mixed, or in part unripe barley. Take a bowl of water, throw into it a couple of handfuls of the malt, giving it a gentle stirring, and the barley which has not been malted will sink to the bottom; the half-malted grains will have one end sunk, being in a vertical position; and the true good malt swim. It is, however, remarked, that the same barley, though ever so good, will not malt alike well at all times: for instance, take it as soon as it is housed, it comes well, but while it is in its sweat, by no means so; yet after it has done sweating, it comes well again, and barley which has been got in early in a very dry season, makes but indifferent malt; while the same barley, if it is left abroad till rain falls on it to loosen the husk from the kernel, malts very well, and yields a large increase. Also old barley, mixed with that of the last harvest, does not malt well, as it does not all spire or put forth its beard, at the same time. These niceties, though little attended to, are of importance in the making of good malt in all cases.

Several regulations relating to the manufacture and sale of malt are enacted by various and successive acts of the British legislature; of which the principal are as follow.

By 12 Ann. stat. 1. cap. 2, continued yearly, and by 33 Geo. II. cap. 7, there shall be paid by the maker for all malt made in England, except it be made for exportation only (12 Geo. c. 4.) a duty of nine-pence a bushel: and by 19 Geo. III. c. 25, an additional duty of 15*l.* per cent. which duty is under the management of the commissioners and officers of excise. (See TAX, *Malt*.) By 43 Geo. I. I.

c. 69, additional duties are likewise imposed. The last annual malt act is the 50 Geo. III. c. 1. Every maltster shall take out a licence from the office of excise annually, paying for the same 5s., if the quantity of malt made by him shall not exceed within the year, ending the 23d of June in each year previous to his taking out such licence, the quantity of 50 quarters.

			£.	s.	d.

and a burcharge.

And every person who shall first become a maltster, for every such licence 5s. and within 10 days after the 5th of July next after taking out such licence, such further additional sum as with the said 5s. shall amount to the duty hereinbefore charged, according to the quantity of malt made by him within the preceding year. (43 Geo. III. c. 69.) If he shall neglect to take out such licence and renew the same annually, 10 days at least before the end of the year, he shall forfeit 10*l.* (24 Geo. III. c. 41.) No malt shall be imported, on pain of forfeiting the same and its value. (12 Ann. stat. 1. c. 2.) By the same act places for making malt are to be entered, on pain of 50*l.*

The maltster is required to give 24 hours notice within a city or market town, and elsewhere 48 hours notice in writing to the officer, of the time of the day when he intends to wet the corn to be made into malt; and he shall not begin but between eight in the morning and two in the afternoon: nor empty any grain out of the cistern, &c. used for wetting or steeping, except between seven in the morning and four in the afternoon: the omission of such notice, &c. incurs a forfeiture of 100*l.* by 3 Geo. III. c. 13. 42 Geo. III. c. 38. 48 Geo. III. c. 74.

Out of every 20 bushels of malt, gauged and charged upon the floor, after the same shall have been taken out of the cistern or other utensil, by the space of 26 hours or more, and before it shall be dried upon the kiln, shall be allowed 10 bushels, and so in proportion for any greater or less quantity. But if corn be continued under water for 40 hours, before the water be taken from it, the maltster shall not be entitled to the said allowance. (42 Geo. III. c. 38. 33 Geo. II. c. 7.) Every round bushel, with a plain bottom, 18½ inches wide throughout, and eight inches deep, shall be deemed a legal Winchester bushel. (12 Ann. stat. 1. c. 2.) No maltster shall wet, sprinkle, &c. any corn or grain in the process of being made into malt, after the same has been emptied out of the steeping vessel, until the expiration of 12 days, or 288 hours, on pain of 200*l.* (48 Geo. III. c. 74.) And if malt be wetted after it hath been taken from the kiln, and before it be delivered to the brewer who may have agreed for the same, except in the ordinary process of brewing beer from such malt; every such offence shall incur a forfeiture of 100*l.* (42 Geo. III. c. 38.) And by 48 Geo. III. c. 74, the penalty incurred by every workman, who shall wet corn contrary to the provisions above-mentioned, is 50*l.*, and in default of payment, commitment to the house of correction for a term, not exceeding 12 months. But

a maltster may drain water from grain whilst steeping before the expiration of 40 hours after being first wetted; provided that no such water shall be drained unless the maltster shall have given notice of the same and the precise time between eight in the morning and four in the afternoon; nor shall the water be drained more than once during the said space of 40 hours, and such corn or grain shall be again completely covered with water within one hour from the beginning so to drain. (42 Geo. III. c. 38.) Servants of maltsters beginning to wet or remove any corn or grain, in a manner contrary to this act, may be fined 50*l.* by any justice, who may commit him for non-payment. (48 Geo. III. c. 74.) By 42 Geo. III. c. 38, excise officers may at all times enter every malt-house or place used for the making of malt, and survey; and the penalty of obstruction is 200*l.* (See 44 Geo. III. c. 34.) And if the officer shall refuse or neglect (after demand in writing, 12 Geo. II. c. 28.) to leave a copy of the gauge for the maker at the time of taking it, he shall forfeit 40*s.* The officer shall measure corn making into malt by the gauge only, and not by the bushel. (12 Ann. st. 1. c. 2.) By 2 & 3 Edw. VI. c. 10, no person shall make any barley malt, except in June, July, and August, which shall not be three weeks at least in making; nor in these months, under 17 days, (unless it be for his own house,) on pain of forfeiting for every quarter 2*s.*; and selling of malt, which has not been well dressed, so that there may not be fanned out of one quarter half a peck of dust or more, incurs a forfeiture of 20*l.* for every quarter; and mixing bad malt with good for sale is liable to a forfeiture of 2*s.* for every quarter. In the process of malting; pressing of malt in the cistern to prevent its swelling, mixing corn of one wetting with corn of a former wetting, and mixing malt with unmalged corn, incur each of them a penalty of 5*s.* a bushel. (1 Geo. III. c. 3. 2 Geo. II. c. 1. 1 Geo. I. c. 2. 48 Geo. III. c. 74.) Again, mixing of malt that has been gauged with the ungauged, subjects to a forfeiture of 200*l.* (1 Geo. III. c. 3.) By 48 Geo. III. c. 74, if any maltster shall tread, ram, or otherwise force together in the cistern, &c. any grain steeping or steeped in order to its being made into malt, he shall forfeit 100*l.* instead of the sum of 5*s.* for every bushel of corn or grain steeping or steeped, that shall be so trodden, &c. mentioned in 48 Geo. III. c. 2; and if any corn or grain, in the process of making malt, be found so hard and compact, as to manifest its having been forced together for preventing its rising and swelling, the maltster, &c. in such case shall forfeit 100*l.*

If any maltster, &c. shall fraudulently conceal any grain making into malt from the view of the gauger, or officer appointed to take an account of the same, he shall forfeit 200*l.* (48 Geo. III. c. 74.) And any maltster fraudulently conveying away from the cistern, &c. any steeping or part of any steeping of corn making into malt, so that no gauge can be taken in the back by the officer, shall forfeit 100*l.* (1 Geo. III. c. 3. 48 Geo. III. c. 74.) By the latter act, the penalty for erecting or extending cisterns, &c. for the manufacture of malt, without previous notice, is 200*l.* The maltster is required to make monthly entry at the office of excise of all the malt made by him in such month (for sale or not for sale), on pain of 100*l.* (12 Ann. stat. 1. c. 2. 44 Geo. III. c. 34.) By 48 Geo. III. c. 74, every maltster shall within the space of 14 days, next after the time of entry (as before) clear away all the duties, unless security shall have been given, to the satisfaction of the commissioners of excise, by bond in double the value of such duties as are likely to become due within any five months, for the due payment

payment at the end of every four months at the day of entry, and if such security be not given, and any maltster, &c. neglect to clear off at the end of 14 days such sums as shall have become due, he shall for every such offence forfeit double the duties.

A drawback of the duty is allowed for malt damaged in exportation, and also for malt destroyed by fire or water. (12 Ann. stat. 1. c. 2.) By the 12 Geo. c. 4. and 33 Geo. II. c. 7, no malt entered and made for exportation shall be liable to the duties, and no drawback shall be allowed for any malt exported. By 1 Geo. III. c. 3, and 44 Geo. III. c. 16, there shall be allowed for every 20 quarters of grain made into malt for exportation 30 quarters of malt and no more, on exportation: and notice shall be given of sleeping and the quantity, on pain of 50*l.* and this shall be kept separate from that designed for home consumption, on pain of 5*l.* a bushel, (12 Geo. c. 4.) and the corn of one sleeping shall be kept separate from any other, until it hath been measured, on pain of 50*l.* (3 Geo. II. c. 7.) Persons opposing officers shall forfeit 50*l.* (12 Geo. c. 4.) Notice of measuring shall be given; and the malt carried on ship-board, or kept separate and locked up, on pain of 50*l.* (12 Geo. c. 4. 3 Geo. II. c. 7. 50 Geo. III. c. 1.) Opening such locks, and carrying away the malt, without consent of the officer, or notice given to him, incur a forfeiture of 100*l.* (3 Geo. II. c. 7. 50 Geo. III. c. 1.) The officer having received 40 hours notice shall attend, keep an account of the malt delivered out, and of the person to whom it belongs, and give a certificate to the officer of the division to which it is to be removed, who shall file the same and make entry thereof: and if the proprietor neglect to deliver such certificate, he shall forfeit 50*l.* (12 Geo. c. 4.) Those intending to ship malt for exportation shall give 48 hours notice to the officer of the port in writing, with the name of the ship, on pain of 5*l.* a bushel. The ship shall be locked, and persons breaking open the hatches, forfeit 50*l.* The landing of malt after shipping for exportation, subjects, besides the penalty of the bond for its exportation, to a forfeiture of the same, and treble the value. (1 Geo. III. c. 3. 50 Geo. III. c. 1.) Storehouses shall be cleared out in 15 months, on pain of 50*l.* Unmalted oats or barley mixed among malt for exportation incurs a forfeiture of 5*l.* a bushel. (6 Geo. c. 21.) If ground malt shall be exported, it shall be computed at so many bushels as it contained before it was ground. (12 Ann. st. 1. c. 3.) The penalties relating to this article (unless otherwise directed) shall be sued for, levied and mitigated as by the laws of excise, or in the courts at Westminster; half to the use of the king, and half to him that shall sue. (6 Geo. c. 21. 24 Geo. II. c. 40. 44 Geo. III. c. 38.) Persons aggrieved may appeal to the next quarter sessions, giving six days notice in writing. (12 Ann. st. 1. c. 2. 1 Geo. II. st. 2. c. 16.) The act 48 Geo. III. c. 74. has made several alterations of the penalties and regulations pertaining to the making of malt, and enacted several provisions by which maltsters and makers of malt are to ascertain, and make entry of the quantity of barley in their possession, and also other provisions for rendering appeals more certain; for which we refer to the act itself. (See BARLEY and CORN.)

The infusion of malt has been much recommended as an antiscorbutic. See SCURVY and WORT.

Good malt may be made of the grain of the maize or Indian corn, but then a particular method must be taken for the doing it. Our barley malt makers have tried all their skill to make good malt of it in the ordinary way, but to no purpose; that is, the whole grain will not be this way

malted or rendered tender and floury, as in other malt; for it is found, by experience, that this corn, before it be fully malted, must sprout out both ways, that is, both root and blade, to a considerable length, that of a finger at least and if more the better. For this purpose it must be laid in a heap a convenient time; and in this process, if it be of a sufficient thickness for coming, it will quickly heat and grow mouldy, and the tender sprouts will be so entangled, that the least moving of the heap will break them off; and the farther maturation of the grain into malt, will be hindered by this means; and on the other hand, if it be laid thin, and often stirred and opened to prevent too much heating, those sprouts which have begun to shoot cease growing, and consequently the corn again ceases to be promoted to the mellowness of malt. Phil. Trans. N^o 142.

To avoid all these difficulties, the following method is to be used: take away the top of the earth in a garden or field, two or three inches, throwing it up half one way, and half the other; then lay the corn for malt all over the ground so as to cover it; the earth that was pared off is now to be laid on again, and nothing more is to be done till the field is all over covered with the green shoots of the plant. The earth is then to be taken off, and the roots of the grain will be found so entangled together, that they will come up in large cakes or parcels; it must be gently washed in order to take off all the dirt, and then dried on a kiln, or on a clean floor exposed to the sun. Every grain of the maize will be thus transmuted into good malt, and the beer brewed with it will be very pleasant and very wholesome, and of an agreeable brown colour, but very clear.

It may be worth trying whether the same process is not with due care applicable to the making of turnips, potatoes, carrots, parsnips, and the like. It might possibly be of service also to attempt this less laborious way of making malt of barley and other small grains: the disadvantages would be the not so easily separating the dirt from the grain as in the larger kind; and as barley requires the root only, not the ear, to shoot in order to the making of malt, it would be some difficulty to know the exact time of taking it up; but with all these disadvantages the method is worth a trial.

MALT-Dust, in *Agriculture*, the dust or substance that separates from the malt in the act of drying, or during its preparation. It is sometimes called malt-combs, and has been found useful as a manure, in lessening the cohesion of stiff heavy soils. But it may probably be made use of to the greatest advantage, as a top dressing when sown over crops in the early spring season. The following experiments are recorded, with respect to the disputed point of its being more adapted to barley than wheat crops. It has often been asserted, by some, that malt-dust is much better suited as a manure to barley than wheat; as from the latter lying a whole year in the ground, and the malt-dust being sown with it, the virtues of the manure are exhausted long before the summer, when the corn principally wants nourishment; being too early advanced in its growth, and rendered winter-proud by it; while others, contradicting this assertion, say it is best for wheat, making it appear, that it often causes very good crops of corn, particularly after a hard winter. In order to make some experiments to ascertain this matter, a field of ten acres was fixed upon, which had borne a good crop of horse-beans; after which it was sown with turnips which, being fed off, it was summer-fallowed, being intended for wheat. The soil was a stiffish loam, in good heart, and tolerably clean. It was divided

by deep furrows into ten equal parts, each containing one acre, and numbered 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10. The whole field during the course of the fallowing had four ploughings given it, which reduced it to a fine tilth or mould. As wheat-feed time came, No. 1 was sown broadcast, with three bushels of wheat, and ploughed in, laying on no manure whatever. No. 2 was sown with the same quantity of wheat, after which ten quarters, or eighty bushels, of malt-duft were strewed over it, and that and the seed ploughed in together. No. 3 was also sown with wheat in the same manner, except that the strewing on the malt-duft was deferred till the latter end of January. No. 4 had a dressing of dung in the ordinary way, and was sown with three bushels of wheat like the other parts. No. 5 was dressed by sheep-folding, and was also in like manner sown with wheat. No. 6 was sown with wheat in the same quantity: and in February, after sowing, received a half dressing of very rotten dung which had been several times turned and mixed. No. 7, after receiving a ploughing in the spring, was sown with ten pecks of barley, which was harrowed in, and no manure at all applied. No. 8 was sown with barley, as above, but had ten quarters of malt-duft laid on it. No. 9 had in the winter a good dressing of dung, and was in the spring sown with the same quantity of barley. No. 10 was sown with barley, like No. 8, only it had five instead of ten quarters of malt-duft laid on it.

It is observed, that all the pieces of wheat were sown the first week in October, and all the barley the second week in March. In January, on examining the wheat, it was found that the acre marked No. 2 looked most forward and flourishing; though there was in appearance but little difference between that and No. 4. The Nos. 1, 3, and 6, neither of them looked so vigorous as those already-noticed; and No. 5 seemed rather thin on the land; but the wheat-plants were in good condition and healthy. And on another examination in May, of the wheat-crops, it was found that No. 1 was tolerably clean and promised well; and No. 2 gave hopes of a large crop, and was surprisingly clear of weeds. No. 3 was greatly improved since the laying-on of the dressing of malt-duft. No. 4 looked very vigorous and strong, but was very foul, having several sorts of weeds not to be met with in other parts of the land. No. 5 was thin of plants, and they did not branch much: however, they still seemed healthy and strong. No. 6 was like No. 3, greatly improved; but it was foul, and what appeared strange, had many weeds of a nature quite different from those with which No. 4 was infested, though the dung laid on both these parts was taken from the same heap.

And at this time, on looking at the pieces sown with barley, No. 7 was found promising and clean. No. 8 was forwarder, and afforded the prospect of a large crop. No. 9 was forward and fine, but foul with weeds. No. 10 bore much the same appearance as No. 1, and promised well.

At harvest, No. 2 of the wheat was first fit to reap, after which succeeded No. 4; the rest were ready nearly at the same time.

Of the barleys, Nos. 8 and 10 were first ready to mow.

It is almost unnecessary to observe, that those crops which were clearest of weeds were the soonest fit for carrying.

These crops were all laid separately, as well as all separately threshed, and dressed as early as possible in the winter.

The produce of the several crops, on being distinctly noted, were the following:

Vol. XXII.

Crops.	Produce.	
	Bushels.	Pecks.
No. 1, manured, wheat	20	1
— 2, manured with malt-duft when sown	28	3
— 3, manured with malt-duft after Christ-mas, by way of top-dressing	40	1
— 4, manured with dung in the ordinary way	32	2
— 5, folded with sheep	29	3
— 6, dressed with rotten dung in February	30	0
— 7, unmanured barley	32	3
— 8, manured with ten quarters of malt-duft when sown	48	0
— 9, manured with dung in the winter	40	2
— 10, manured when sown, with five quarters of malt-duft	44	0

From these trials it is concluded, first, that when malt-duft is used as a manure for wheat, it is the best to lay it on by way of top-dressing after the corn is come up, as the crop of No. 3 yielded above twelve bushels more than that of No. 2; and it is supposed that the virtue of the malt-duft laid on No. 2 was exhausted before it could be of any essential service to the crop, whereas, in No. 3 the manure began to yield forth its virtues just as the wheat-plants began to be in want of a fresh supply of nourishment. It was also evident, that the grains of wheat which grew on No. 2 were thinner and had less substance than those of No. 3, the grain of which was fine, plump, and heavy.

It was also clear, from the produce of No. 4, that malt-duft is, in many cases, a better manure for wheat than dung, not only as it gives a larger increase, but also because it does not stock the land with destructive and devouring weeds.

The wheat grown on No. 5, was as fine as that of No. 3, but considerably less in quantity, as appears by the account.

The method pursued in No. 6 is not desirable: it is a good alternative, if the farmer happens to have too little dung to dress all his fallow-lands with.

It is also supposed that malt-duft is a very good and profitable manure for a barley crop; but the yielding of No. 10 being forty-four bushels, and of No. 8 only forty-eight bushels, which last is not an increase in proportion to the additional quantity of manure laid on, it may be concluded, that eight quarters, or sixty-four bushels, of malt-duft is the proper quantity to lay on an acre for a barley crop, and that at the time of sowing. In speaking of malt-duft, it is meant the kiln-duft, or that which falls from the malt in drying: as to the tail-duft, that falls through the screen whilst the malt is cleaning before it is put in sacks, that may be applied to a better use, being generally given to pigs, and often to cows, in which last case it makes them give a great deal of milk.

It has been suggested that the virtue of malt-duft, as a manure, lasts only for one crop; but this is a mistake, for when the manure is laid on in January or February, a good crop of the green kind may be had after the wheat.

This manure is supposed to be of a very warm nature; this has induced many farmers to think that it may burn crops; and it may, perhaps, do so on a hot gravelly soil; but on clay land or a stiff loam, it seldom or ever does any damage: and indeed the only danger is a dry time ensuing after it is spread on the land, for the first shower of rain washes it in, and secures the crop from all hazard of being burnt or injured in that way.

It is supposed by some, that malt-duft is for a stiff soil a better

a better manure than dung; but the difficulty is, whether it is most profitable to lay it on when the wheat is sown, or by way of top-dressing in January or February. The above experiments seem to shew, that the best time to dress heavy land with it, is in January or the following month.

It is also stated, that nothing surpasses this manure when laid on cold grass grounds, to the amount of about eight quarters or sixty bushels an acre. Its effects in this way are said to be very great.

In an experiment of Mr. Bedford's, in which a piece of land was manured with this substance at the rate of four quarters to the acre, and sown with barley and clover, the barley was very luxuriant, producing near seven quarters *per* acre, and the clover extremely fine; from which it is concluded, that it is a valuable sort of manure, being cheaper than rape-dust or any other sort of top-dressing, as it only costs about twelve shillings the acre.

About Dunstable this sort of manure costs one shilling a bushel, is sown by hand at the rate of from twenty-four to thirty-two bushels the acre over the barley land, and harrowed-in with the seed. It is seldom used to wheat in that district, but would probably answer well to it as a top-dressing, in the proportion of about thirty bushels to the acre, sown over the crops in March.

The black malt-dust, or that which falls through the kiln-plate, is preferable to the white, from the seeds of weeds being destroyed by the heat in drying.

MALT, for the manner of preparing liquors of, see BREWING.

MALT Liquors have different names as well as different virtues, properties, and uses, both from the different manners of preparing the malt, whence they are distinguished into *pale* and *brown*; and from the different manners of preparing or brewing the liquors themselves, whence they are divided into *beer* and *ale*, *strong* and *small*, *new* and *old*.

Malt drinks are either pale or brown, as the malt is more or less dried on the kiln; that which is the slenderest dried, tinging the liquor least in brewing, and therefore being called *pale*: whereas that higher dried, and as it were roasted, makes it of a higher colour. A mixture of both these makes an amber colour; whence several of these liquors take their name.

Now, it is certain, the pale malt has most of the natural grain in it, and is therefore the most nourishing; but for the same reason, it requires a stronger constitution to digest it. Those who drink much of it, are usually fat and sleek in their bloom, but are often cut off by sudden fevers; or, if they avoid this, they fall early into a ditterpered old age.

The brown malt makes a drink much less viscid, and fitter to pass the several strainers of the body; but, if very strong, it may lead on to the same inconveniences with the pale; though a single debauch wears off much more easily in the brown.

Dr. Quincy observes, that the best pale malt liquors are those brewed with hard waters, as those of springs and wells, because the mineral particles, with which these waters are impregnated, help to prevent the cohesions of those drawn from the grain, and enable them to pass the proper secretions the better; as the viscid particles of the grain do likewise defend these from doing the mischief they might otherwise occasion. But softer waters seem best suited to draw out the substances of high-dried malts, which retain many fiery particles in their contexture, and are therefore best lost in a smooth vehicle.

For the differences in the preparation of malt liquors, they

chiefly consist in the use of hops, as in beer; or in the more sparing use of them, as in ale.

The difference made by hops is best discovered from the nature and quality of the hops themselves: these are known to be a subtle grateful bitter: in their composition, therefore, with this liquor, they add somewhat of an alkaline nature, *i. e.* particles that are sublime, active, and rigid. By which means, the rosy viscid parts of the malt are more divided and subtilized; and are, therefore, not only rendered more easy of digestion and secretion in the body, but also, while in the liquor, they prevent it from running into such cohesions as would make it rosy, vapid, and sour.

For want of this, in unhopped drinks, that clammy sweetness, which they retain after working, soon turns them acid, and unfit for use; which happens sooner or later, in proportion to the strength they receive from the malt, and the comminution they have undergone from fermentation.

It is a common opinion, that ale is more diuretic than beer, that is, liquor less hopped more than that with a greater quantity of hops in it: which may hold in some constitutions, because ale being more smooth, softening, and relaxing, where urine is to be promoted by enlarging the passage, as in thin, dry constitutions, this is the most likely to effect it. But where the promoting of urine is to be done by attenuating and breaking the juices, and rendering them more fluid, it is certainly best answered by those drinks which are well hopped.

As to the dispute, whether or no hops tend to breed the stone, it is too long to enter upon here. Quincy is of opinion, there is but little reason for the affirmative side of the question; and, in general, makes no scruple to say that, for one constitution damaged by beer, there are numbers spoiled by ale. This last manifestly fouls the glands, stuffs the vessels with slime and viscidities, makes the body unwellish and corpulent, and paves the way for cachexies, jaundice, asthma, and at last incurable dropies. The urinary passages, also, which it is supposed to clear, will, in time, be filled by it with slough, and matter of as ill consequence as gravel.

The different strengths of malt liquors also make their effects different. The stronger they are, the more viscid parts they carry into the blood; and though the spirituous parts make these imperceptible at first; yet when those are evaporated, which will be in a few hours, the other will be sensibly felt by pains in the head, nausea, and sickness at the stomach, and lassitude or listlessness to motion. This, those are the most sensible of, who have experienced the extremes of drinking these liquors and wines; for a debauch of wine they find much sooner worn off, and they are much more lively and brisk afterwards, than after intemperately using malt liquors, whose viscid remains will be long before they be shaken off.

Malt liquors, therefore, are, in general, the more wholesome for being small, *i. e.* of such a strength as is liable to carry a small degree of warmth into the stomach, but not so great as to prevent their being proper diluters of the necessary food. Indeed, in robust people, or those who labour hard, the viscidities of the drink may be broken into a convenient nourishment; but in persons of another habit and way of living, they serve rather to promote obstructions and ill humours.

The age of malt liquors is the last thing by which they are rendered more or less wholesome. Age seems to do nearly the same thing as hops; for those liquors which are longest kept are certainly less viscid; age breaking the viscid

acid parts, and, by degrees, rendering them smaller, and fitter for secretion.

But this is always determined according to their strength; in proportion to which, they will sooner or later come to their full perfection, as well as decay; for, when ale or beer is kept till its particles are broken and comminuted as far as they are capable, then it is that they are best; and, beyond this, they will be continually on the decay, till the finer spirits are entirely escaped, and the remainder becomes vapid and sour.

MALT Distillery. This is an extensive article of trade, and by which very large fortunes are made. The art is to convert fermented malt liquors into a clear inflammable spirit, which may be either sold for use in the common state of a proof strength, that is, the same strength with French brandy; or is rectified into that purer spirit usually sold under the name of spirit of wine; or made into compound cordial waters, by being distilled again from herbs and other ingredients. See BREWING, SPIRITS, and WASH.

To brew with malt in the most advantageous manner, it is necessary, 1. That the subject be well prepared; 2. That the water be suitable and duly applied; and, 3. That some certain additions be used, or alterations made, according to the season of the year, and the intention of the operator; and by a proper regulation in these respects, all the fermentable parts of the subject will thus be brought into the tincture, and become fit for fermentation.

The due preparation of the subject consists in its being justly malted and well ground. When the grain is not sufficiently malted it is apt to prove hard, so that the water can have but very little power to dissolve its substance; and if it be much malted, a part of the fermentable matter is lost in that operation. The harder and more stinty the malt is, the finer it ought to be ground; and in all cases, when intended for distillation, it is advisable to reduce it to a kind of finer or coarser meal. When the malt is thus ground, it is found, by experience, that great part of the time, trouble, and expence of the brewing is saved by it, and yet as large a quantity of spirits will be produced; for thus the whole substance of the malt may remain mixed among the tincture and be fermented and distilled among it. This is a particular that very well deserves the attention of the malt distiller, as the trade is at present carried on; for the dispatch of the business, and the quantity of spirit procured, are more attended to than the purity or perfection of it.

The secret of this matter depends upon the thoroughly mixing, or briskly agitating and throwing the meal about, first in cold, and then in hot water; and repeating this agitation after the fermentation is over, when the thick turbid wash being immediately committed to the still, already hot and dewy with working, there is no danger of burning, unless by accident, even without the farther trouble of stirring, which in this case is found needless, though the quantity be ever so large, provided that requisite care and cleanliness be used; and thus the business of brewing and fermenting may very commodiously be performed together, and reduced to one single operation. Whatever water is made choice of, it must stand in a hot state upon the prepared malt, especially if a clear tincture be desired, but a known and very considerable inconvenience attends its being applied too hot, or too near to a state of boiling, or even scalding with regard to the hand. To save time in this case, and to prevent the malt running into lumps and clods, the best way is to put a certain measured quantity of cold water to the malt first; the malt is then to be stirred very well with this, so as to form a sort of thin uniform paste or

pudding; after which the remaining quantity of water required may be added in a state of boiling, without the least danger of making what, in the distillers language, is called a pudding.

In this manner the due and necessary degree of heat in the water, for the extracting all the virtues of the malt, may be hit upon very expeditiously, and with a great deal of exactness, as the heat of boiling water is a fixed standard which may be let down to any degree by a proportionate mixture of cold water, due allowances being made for the season of the year, and for the temperature of the air.

This little obvious improvement, added to the method just above hinted for the reducing brewing and fermentation to one operation, will render it practicable to very considerable advantage, and the spirit improved in quality as well as quantity.

A much more profitable method than that usually practised for the fermenting malt for distillation, in order to get its spirit, is the following: Take ten pounds of malt reduced to a fine meal, and three pounds of common wheat-meal: add to these two gallons of cold water, and stir them well together, then add five gallons of water boiling hot, and stir all together again. Let the whole stand two hours, and then stir it again, and when grown cold, add to it two ounces of solid yeast, and set it by loosely covered in a warmish place, to ferment.

This is the Dutch method of preparing what they call the wash for malt spirit, whereby they save much trouble, and procure a large quantity of spirit: thus commodiously reducing the two businesses of brewing and fermenting to one single operation. In England the method is to draw and mash for spirit as they ordinarily do for beer, only instead of boiling the wort, they pump it into large coolers, and afterwards run it into their fermenting backs, to be there fermented with yeast. Thus they bestow twice as much labour as necessary, and lose a large quantity of their spirit by leaving the gross bottoms out of the still for fear of burning.

All simple spirits may be considered in their different states of low wines, proof spirit, and alcohol, the intermediate degrees of strength being of less general use; and they are to be judged of only according as they approach to, or recede from, these. Low wines, at a medium, contain a sixth part of pure inflammable spirit, five times as much water as spirit necessarily arising in the operation with a boiling heat. Proof goods contain about one-half of the same totally inflammable spirit; and alcohol entirely consists of it. See SPIRITS.

Malt low wines, prepared in the common way, are exceedingly nauseous; they have, however, a natural vinosity, or pungent agreeable acidity, which would render the spirit agreeable to the palate, were it not for the large quantity of the gross oil of the malt that abounds in it. When this oil is detained in some measure from mixing itself among the low wines, by the stretching a coarse flannel over the neck of the still, or at the orifice of the worm, the spirit becomes much purer in all respects; it is less fulsome to the taste, less offensive to the smell, and less milky to the eye. (Shaw's Essay on Distillery.) When these low wines, in the rectification into proof spirits, are distilled gently, they leave a considerable quantity of this gross fetid oil behind them in the still along with the phlegm; but if the fire be made fierce, this oil is again raised and brought over with the spirit; and being now broken somewhat more fine, it impregnates it in a more nauseous manner than at first. This is the common fault both of the malt distiller and

of the rectifier; the latter, instead of separating the spirit from this nasty oil, which is the principal intent of his process, attends only to the leaving the phlegm in such quantity behind, that the spirit may be of the due strength as proof or marketable goods, and brings over the oil in a worse state than before. To this inattention to the proper business of the process, it is owing that the spirit, after its several rectifications, as they are miscalled, is often found more stinking than when delivered out of the hands of the malt distiller. All this may be prevented by the taking more time in the subsequent distillations, and keeping the fire low and regular, the sudden stirring of the fire, and the hasty way of throwing on the fresh fuel, being the general occasions of throwing up the oil by spurts, where the fire in general, during the process, has not been so large as to do that mischief.

The use of a *bañum Mariæ*, instead of the common still, would effectually prevent all this mischief, and give a purer spirit in one rectification, than can otherwise be procured in ten, or indeed according to the common methods at all.

Malt low wine, when brought to the standard, or proof spirit, loses its milky colour, and is perfectly clear and bright, no more oil being contained in it than is perfectly dissolved by the alcohol, and rendered miscible with that proportion of phlegm, which is about one-half the liquor; its taste also is cleaner though not more pleasant; there being less of the thick oil to hang on the tongue in its own form, which is not the case in the low wines, where the oil, being undissolved, adheres to the mouth in its own form, and does not pass lightly over it.

When proof spirit of malt is distilled over again, in order to be rectified into alcohol, or, as we usually call it, spirits of wine, if the fire be raised at the time when the fumes begin to come off, a very considerable quantity of oil will be raised by it, and will run in the visible form of oil from the nose of the worm. This is not peculiar to malt spirit, but the French brandy shews the same phenomenon, and that in so great a degree, that half an ounce of this oil may be obtained from a single piece of brandy.

Malt spirit, more than any other kind, requires to be brought into the form of alcohol, before it can be used internally, especially as it is now commonly made up in the proof state, with as much of this nauseous and viscous oil as will give it a good crown of bubbles. For this reason it ought to be reduced to an alcohol, or totally inflammable spirit, before it is admitted into any of the medicinal compositions. If it be used without this previous caution, the odious taste of the malt oil will be distinguished among all the other flavours of the ingredients.

Malt spirit, when it has once been reduced to the true form of an alcohol, is afterwards more fit for all the curious internal uses than even French brandy, it being after this purification a more uniform, hungry, tasteless and impregnable spirit, than any other spirits which we esteem so much finer.

A pure spirit being thus procured, should be kept carefully in vessels of glass or stone, well stopped to prevent the evaporation of any of its volatile part. If preserved in casks, it is apt to impregnate itself very strongly with the wood. The quantity of pure alcohol obtainable from a certain quantity of malt, differs according to the goodness of the subject, the manner of the operation, the season of the year, and the skilfulness of the workman; according to which variations, a quarter of malt will afford from eight or nine, to thirteen or fourteen gallons of alcohol. This should encourage the malt distiller to be careful and diligent

in his business, as so very large a part of his profit depends wholly on the well conducting his processes.

After every operation in this business, there remains a quantity of fumes, which in their own coarse state ought never to be admitted into the true spirit; these are to be saved together, and large quantities of them at once wrought into alcohol. It is easy to reduce these to such a state, that they will serve for lamp spirits. Their disagreeable flavour being corrected by the adding of aromatics during the distillations, the reducing them to a perfect and pure alcohol is practicable, but not without such difficulties, as render it scarcely worth the trader's while. One way of doing it is by distilling them from water into water, and that with a very slow fire. By this means a pure alcohol may be made out of the foulest fumes.

The malt distiller always gives his spirit a single rectification *per se*, in order to purify it a little, and make it up proof, but in this state it is not reckoned fit for internal uses, but serves to be distilled into geneva and other ordinary compound strong waters for the vulgar.

The Dutch, who carry on a great trade with malt spirit, never give it any farther rectification than this, and it is on this account that the malt spirit of England is in general so much more in esteem. The Dutch method is only to distil the wash into low wines, and then to full proof spirit; they then directly make it into geneva, or else send it as it is to Germany, Guinea, and the East Indies, for the Dutch have little notion of our rectification. Their spirit is by this means rendered very foul and coarse, and is rendered yet more nauseous by the immoderate use they make of rye meal. Malt spirit, in its unrectified state, is usually found to have the common bubble proof, as the malt distiller knows that it will not be marketable without it.

The whole matter requisite to this is, that it have a considerable portion of the gross oil of the malt well broke and mixed along with it; this gives the rectifier a great deal of trouble if he will have the spirit fine; but in the general run of the business, the rectifier does not take out this oil, but breaks it finer, and mixes it faster in by alkaline salts, and disguises its taste by the addition of certain flavouring ingredients. The spirit loses in these processes the vinosity it had when it came out of the hands of the malt distiller, and is, in all respects, worse, except in the disguise of a mixed flavour. *Shaw's Essay on Distillery.*

The alkaline salts used by the rectifier, destroying the natural vinosity of the spirit, it is necessary to add an extraneous acid in order to give it a new one. The acid they generally use is the *Spiritus nitri dulcis*; and the common way of using it is the mixing it to the taste with the rectified spirit: this gives our malt spirit, when well rectified, a flavour somewhat like that of French brandy, but this soon flies off; and the better method is to add a proper quantity of Glauber's strong spirit of nitre to the spirit in the still. The liquor in this case comes over impregnated with it, and the acid being more intimately mixed, the flavour is retained. See *SPIRITUS nitri dulcis*.

MALTA, in *Geography*, anciently *Ogygia* and *Melite*, from which latter the Saracens have formed *Malta*, an island in the Mediterranean, about fifty miles from the coast of Sicily, twenty miles long, and twelve miles in its greatest breadth, and about sixty miles in circumference. It consists of an immense white soft rock of free-stone, covered with a thin stratum of earth, most of which has been brought from Sicily, seldom more than a foot above the surface of the rock; and this earth is removed once in ten years,

years, in order to clear the rock of a thick crust which forms, and prevents the moisture from sufficiently penetrating. It was anciently reckoned a part of Africa, but now belongs to Europe. The soil, watered by the night-dew and well cultivated, produces cumin-seed, anise-seed, cotton, excellent fruits, such as melons, oranges, lemons, and particularly figs, vegetables, and pastures; but it yields neither grain nor wine sufficient for its inhabitants, who are estimated at about 63 or 64,000, including those in the neighbouring islands. It furnishes plenty of excellent and finely-flavoured honey, sea-salt, considerable fisheries, and a profitable coral-fishery. The island is divided into small inclosures of free-stone, is well planted, and contains several towns and villages; the principal of the former are La Valetta, Citta Vittoriosa, Senglea, Barmola, Citta Nuovo Cottonera, and Malta. The coast is for the most part secured by shelves and perpendicular rocks, without one port or safe road for ships; but on the east and west shores there are several commodious harbours. The two most considerable are those on the S. E. side, one called Marza Murzet, and the other Marza, which signifies *port*, and is the largest of the two. They are divided by an oblong peninsula, on which is built a strong fort or castle, called St. Elmo, which defends the entrance into both. Within that of Murzet lies a small island, near which the ships suspected of infection are obliged to perform quarantine. Those places which are accessible are defended by fortifications of great strength, so that it would be very difficult to reduce it by force. Mortars, the mouths of some of which are six feet wide, are cut out of the rocks near the different creeks, where a debarkation might be attempted. Considerable quantities of sea-shells and fish-bones petrified are found all over the island, even in parts most elevated and remote from the sea.

During summer Reaumur's thermometer is generally below 25°, and seldom above 28°, or from about 88° to 95° of Fahrenheit. In the winter it is seldom lower than 8° below zero of Reaumur's, or 14° of Fahrenheit. The alternate changes from heat to cold are often very sudden. Cold is occasioned by the north and north-west winds; and a south wind brings heat. This wind, passing over the barren sultry continent of Africa, is dangerous, but is of no long duration, and frequently succeeded by a calm, during which the heat is suffocating. Whilst the sirocco continues, iced beverages are copiously used; and, therefore, snow is considered at Malta as one of the necessaries of life. It is brought from Sicily, and administered to the sick; and whenever there is a scarcity, all that remains in the ice-house is entirely reserved for the use of the hospitals. Cold bathing is also successfully used as a preservative against the ill effects of the sirocco.

This island has often changed its masters. Its original inhabitants were the Phœnicians, who were expelled by the Phœnicians, and these again by the Greeks. It next became subject to the Carthaginians, and they were succeeded by the Romans, who established in it a prefect, as he is called in the Acts of the Apostles, ch. xxviii. 7, and this prefect was dependent on the prætor of Sicily. Upon the declension of the Roman empire, it fell under the dominion of the Goths, and afterwards of the Saracens. Roger, the Norman, earl of Sicily, took possession of it about the year 1190; and from that time it continued under the dominion of the kings of Sicily, till it fell under that of Charles V., by his conquest of Naples and Sicily, who gave it in 1525, by a grant which was ratified by the pope in 1530, to the knights of Rhodes, afterwards of Malta. (See the next article.) Charles V. was induced to make this grant by

an ambition of becoming the restorer and second founder of an order, which for many ages had been devoted to the defence of Christians, and also by the hope of thus protecting the isles of Sicily and Sardinia, the kingdom of Naples, and the coasts of Italy from the incursions of the infidels; stipulating with the knights that they should maintain a perpetual war against the Turks and Corsairs. These knights, after their establishment in Malta, fortified the island. Solyman, incensed by observing that his ships were constantly exposed to the attacks of enemies, which he had, in his own imagination, destroyed when he drove them from Rhodes, determined, in 1565, to make an attempt against Malta. For this purpose he sent 30,000 men against the town of Malta, which was defended by 700 knights and 8000 soldiers, under the command of the grand master John de Valette, at the age of seventy-one years. When some of his friends saw that their brave commander was wounded, they intreated him to retire; but he replied, "At seventy-one, can I finish my life more gloriously than by dying with my brethren?" After having sustained a siege of four months, they were relieved by a force of 6000 men, sent from Sicily to their succour, and the Turks were compelled to raise the siege.

Hence this town obtained the name of "Citta Vittoriosa," which it retains to this day: La Valetta was built by La Valette, and called after his name. One of his successors made a magnificent aqueduct in 1616, to bring water to this new city; and others constructed various works of importance to the safety of the place. When the town was finished, the convent and habitation of the knights were removed hither. That the work might not be interrupted, when money failed, they paid in copper, which was afterwards called in at its full value. The inscription on it was, "Non æs sed fides," not money but loan. In process of time this island maintained itself against the whole Ottoman power; but the order was never rich enough to attempt foreign conquests, nor to equip numerous fleets. They were, however, as liberal as they were brave in assisting their neighbours, and also in defending themselves against the Turks and the Corsairs of Algiers and Tripoli. In the year 1724, a truce was concluded with the Turks for twenty-one years, subject to renewal if both parties should think proper. While it continued, the Maltese were to enjoy in the states of the grand seignior the same privileges as the French. They also stipulated for the exchange and ransom of slaves. The sultan agreed not to give any assistance to the states of Barbary; and the treaty was to be void when any of the Christian princes were at war with the Porte. In 1798 the island surrendered to the French, and the knights were dispersed; and in September 1800, it was taken by the British, who retained the possession of it. The principal disadvantages, says Barrow (*Travels in Southern Africa*, vol. ii.), that would result to England by leaving Malta in the possession of the French, appear to be, in the first place, the power it would give them of excluding our ships from that port, undoubtedly the best in the Mediterranean, and of increasing their forces here to the complete destruction of our Mediterranean trade; and, secondly, the means it affords of facilitating their views upon Egypt, by enabling them to throw into that country a force sufficient to renew their project upon India. See the next article.

Before the knights took possession of that island, it was so barren and uninviting, that when Charles V. offered it to them, they sent commissaries to examine, and after their report, they could hardly be induced to accept the grant. But by subsequent exercises of skill and industry, they have

effected a surprising alteration, not only in its means of defence, but in its internal cultivation. The capital of the island is "La Valetta," or Citta Nuova, which is situated on the east coast, and was founded, as we have already observed, in 1566, on an elevated peninsula, having at its extremity the castle of St. Elmo. This town contains the palace of the grand master, the arsenal, the infirmary, the church of the prior of St. John, and hotels for the knights of different languages. On either side of the peninsula is a good harbour. "Citta Vittoriosa" is a fortified town on a narrow point of land that projects into the Marza, or great harbour, opposite to Valetta, and is defended by the strong castle of St. Angelo, standing on a high rock, and communicating with the town by a bridge. In this town was the palace of the inquisition, an arsenal, and a lodgment of slaves; the Greeks have also a church here. "Senglea," or the isle of St. Michael, is a considerable town on a peninsula, separated from Citta Vittoriosa by the canal Porto della Galere, and joined to the harbour by the canal Porto della Rennella. But we must not confound this Malta with old Malta, called "Citta Vecchia." Melita, or Medina, the capital, was a considerable town previous to the arrival of the knights of Rhodes; it is now a small fortified place and bishop's see, containing a cathedral and several religious houses, on an eminence near the centre of the island. In its vicinity are extensive catacombs, which form a labyrinth. "Barmola" is a little town of 700 houses behind Senglea. "Citta Nuova Cottonera" is a regularly fortified town, including the old fort of St. Margherita. The five towns above enumerated, may be considered as portions of one large city, separated from each other by havens, and containing 20,000 inhabitants. The houses are built of stone, flat-roofed, and covered with plaster. The harbours are capable of receiving whole fleets; and, as the situation is naturally strong, no art is wanting to render the fortifications impregnable.

"Forte di S. Thomasso" stands on a point of land projecting into the sea, about two miles S.E. of the capital, "Malta." "Forte Rosso" stands on a peninsula opposite to the island of Comino.

The climate of Malta is not insalubrious: the excessive heat being mitigated by the westerly and north-westerly winds. Although there are no rivers in the island, there are interspersed some excellent springs of fresh water; but where these fail, the people are forced to dig wells in the rock. Their towns are commonly supplied by rain-water, which they preserve in cisterns. Fuel is very scarce, as there is little wood upon the island; so that the common people are under a necessity of using dried cow-dung or wild thistles to dress their meat, heat their ovens, and warm their apartments in cold weather. Although pasturage is scarce, they breed here a great number of sheep and goats, whose flesh is exquisite, as they chiefly feed on aromatic plants that grow on the rocks. Here are hogs in abundance, and good asses, mules, and some horses that are fed with barley and chaff. The poultry are large; those of the wild kind, particularly partridges, come from other countries in large flights, especially in the months of March and October.

The Maltese resemble the inhabitants of Barbary; and their language is nearly the same, being the old Punic or Arabic, which is very differently spoken in different places. But in the city of Valetta and among persons of rank the language most in use is the Italian. The natives are industrious, active, economical, and brave; but they are mercenary, passionate, jealous, superstitious, and vindictive. Their dress in general consists of a cotton shirt, a vest, a cloak, with a

girdle round the waist. They also wear trowsers, and a sort of shoes called "korch," which is merely a leathern sole, with strings to fasten it round the leg. Their cap is white or coloured. They are remarkably temperate; a clove of garlic, or an onion, anchovies dipped in oil, and salted fish, being their usual diet. On great festivals they eat pork.

Their principal trade is in cotton; of which a great quantity is annually exported. The imports are corn, cloth, wood, oil, wine, brandy, &c. As they are seldom without cruisers at sea, their captures of the Turkish and Barbary corsairs constitute the principal branches of their commerce; for they are thus able to furnish Sicily and other parts of the Levant, with spices, sugar, and other commodities, in return for which they bring back grain, pulse, flesh, both fresh and salted, wood, oil, salt, and other necessaries. But the chief profit of these goes to the order, the native inhabitants having no other share than by the exchange they make of them with the produce of their own lands and industry. The forces of the island, exclusive of the knights and those who belong to the order, consist of those who are able to bear arms, and who are in general robust and well disciplined. They are obliged, at the firing of the signal cannon three times, to appear under their proper standards, in all their martial accoutrements. Under the discipline of the Maltese knights, they are become expert in the use of fire-arms. They are also reckoned good horsemen. Every knight that has four scudi *per* day is obliged to maintain a horse for his own use and at his own charge. The number of galleys which the order furnishes is greater or less, according to the exigence of the occasion. These galleys are strongly built, well manned and commanded; having usually each 100 warriors and 25 knights on board; and that, which is called the "Capitania," and carries the standard of the order, has most commonly 30 knights. Besides these, they have a number of galleons, and other inferior vessels, the crews of which consist chiefly of slaves, of whom they have seldom less than two or three thousand. All along the coast the island is well garrisoned and fortified; and on the least appearance of danger, beacons are set on fire on the high grounds, and these signals are answered by the firing of the city guns; so that the alarm is soon spread through the whole island. The grand master has the whole revenue of Malta, as well as of Gozo, over which he is invested with the sovereign power during his life. His revenues arise from a certain tax upon the island, and include the duties on salt goods imported and exported, and such like imports. These, with some additional perquisites, formerly amounted, *communibus annis*, to about 60,000 crowns. Boisselin's Ancient and Modern Malta, &c. 3 vols. 4to.

Malta keeps accounts in scudi of 12 tari, each taro being subdivided into two carlini, 20 grani, or 120 piccioli. These monies of account are valued both in silver money and copper money; meaning by copper money (not metal) but the current value of the coins of the island, and by silver money their value in foreign exchange. Silver money is to copper money as three to two. The gold coins are double, single, and half Louis-d'ors, coined by the grand master Rohan, at 20, 10, and 5 scudi, copper or current money. The silver coins are ounces and half ounces, coined by the same grand master, at 30 and 15 tari; scudi and halves, at 12 and 6 tari; pieces of one, two, and four tari, all in current money. The real copper coins are tari, and pieces of 10, 5, 2½, and 1 grani. Spanish quadruples pass for 38½ scudi; Venetian sequins for 6 scudi; Dutch ducats for 5½ scudi; Sicilian ounces for 6¼ scudi; Spanish dollars

dollars for 30 $\frac{1}{2}$ tari; current or copper money. The fineness both of gold and silver is expressed in carats; but the gold is divided into 24 carats, and the silver into 12. Gold and silver are weighed by the pound of 12 ounces; the ounce is divided into 16 parts, or 32 trapezi; and the trapezo into 18 grani. This pound weighs 4888 English grains; so that 720 lb. or oz. of Malta is = 611 lb. or oz. troy. According to the rate of coinage, the double Louis-d'or is to weigh $\frac{3}{8}$ of an oz. of Malta, or 260 $\frac{1}{2}$ English grains; and the gold is to be 20 $\frac{1}{2}$ carats fine. The ounce or piece of 30 tari is to weigh 1 $\frac{1}{2}$ oz. of Malta, or 458 $\frac{1}{2}$ English grains, and the silver is to be 10 carats (or $\frac{1}{2}$ ths) fine. The scudi and inferior silver coins are almost 9 carats, fine. The single Louis-d'or is worth 19s. 8d. sterling; the piece of 30 tari, or 2 $\frac{1}{2}$ scudi, is worth 53 $\frac{1}{2}$ d. Thus the scudo current money is worth 21 $\frac{1}{2}$ d. sterling.

The commercial weights are the heavy and the light cantaro; the former consisting of 111 heavy rottoli, each of 2 $\frac{1}{2}$ lb.; the latter of 100 light rottoli, each of 2 $\frac{1}{2}$ lb. The heavy cantaro is = 213lb. avoirdupois, and the heavy rottolo = 30 $\frac{1}{2}$ oz. do. The light cantaro = 175lb. avoirdupois; and the light rottolo = 28 oz. do.; 10lb. of Malta = 7lb. avoirdupois.

The measures are a salma of corn, nearly equal to an English quarter, or 64 salma = 63 English quarters: the cassiso, a measure for oil, contains 5 $\frac{1}{2}$ English gallons. The canna, a long measure, is divided into 8 palmi, and is 922 $\frac{1}{2}$ French lines, or 81 $\frac{9}{16}$ English inches; hence 40 canna = 91 English yards. The foot of Malta is 11 $\frac{1}{16}$ English inches, and 72 feet of Malta = 67 English feet. The Sicilian weights and measures are likewise used here, for which see SICILY.

In 1808 the Sicilian dollar of 2 $\frac{1}{2}$ scudi or 30 tari was exchanged for 56 $\frac{1}{4}$ pence sterling, in government bills in England at 30 days sight. Kelly's Universal Cambist, vol. i. N. lat. 35 $^{\circ}$ 42'. E. long. 14 $^{\circ}$ 10'.

MALTA, a town of America, in Saratoga county, New York, taken from the western part of Stillwater; four miles E. of Balltown springs.

MALTA, *Knights of*, an order of military religious, who have borne various other names; as Hospitalers of St. John of Jerusalem, knights of St. John, knights of Rhodes, order of Malta, religion of Malta, &c.

About the year 1048, some Neapolitan merchants founded a church after the Latin rite at Jerusalem, giving it the name of Santa Maria della Latina, or St. Mary of the Latins. They also founded a monastery of religious after the order of St. Bennet, for the reception of pilgrims; and afterwards an hospital near the monastery, to take care of the diseased, under the direction of a master or rector, to be nominated by the abbot of Santa Maria della Latina. Besides which, they also built a chapel in honour of St. John Baptist.

In 1099, Godfrey of Bulloign, having taken Jerusalem, endowed this hospital with some demesnes, which he had in France; and others imitating his liberality, the revenues of the hospital became considerably augmented. Upon this, Gerhard de Didier, a native of Provence, their rector, in concert with the Hospitalers, resolved to separate from the abbot and religious of Santa Maria, and to form a distinct congregation, under the name and protection of St. John Baptist: and hence it was that they had the name of "Hospitalers, or Brothers of St. John of Jerusalem." Their habit was black; and they wore on their breasts a white cross of eight points, in token of the eight beatitudes.

Pope Pascal II. by a bull in the year 1113, confirmed the donations made to this hospital, which he settled un-

der the protection of the holy see; ordering, that the rector, after Gerhard's death, should be chosen by the Hospitalers. Raymond du Puy, Gerhard's successor, took the title of "master;" and he gave a rule to the Hospitalers, which was approved by pope Calixtus II. in 1120. Such was the first rite of the order of Malta.

Their first grand-master, finding the revenues of the hospital vastly to exceed what was necessary for the entertainment of poor pilgrims, and diseased persons, resolved to employ the surplus against the infidels; and with this view he offered himself to the king of Jerusalem.

He divided his Hospitalers into three classes; the first consisted of nobles, whom he destined to the profession of arms, for the defence of the faith, and the protection of pilgrims; the second consisted of priests or chaplains, who were to say mass; and the third of servitors, who were not noble, but were also appointed for the war. He also regulated the manner of admitting knights brothers; and had the whole confirmed in 1130, by pope Innocent II. who commanded that the standard of the knights should be "gules, a full cross argent."

After the loss of Jerusalem, they retired first to Margath, then to Acre, which they defended very vigorously in 1290. After the entire loss of the Holy Land they withdrew to Cyprus, where king Henry of Lusignan, whom they had followed thither, gave them the city of Limission. Here they continued eighteen years, when, taking the island of Rhodes from the Saracens in 1308, they settled there. And now it was that they first took the name of "knights," and soon after "knights of Rhodes."

Andronicus, emperor of Constantinople, granted to their grand master, Fulk de Villaret, the investiture of this order, and the donation was confirmed by pope Clement. The year following, with the assistance of Amadeus IV. duke of Savoy, they defended themselves, and their island against an army of Saracens. In 1480, their grand master d'Aubusson made a vigorous defence against Mahomet II. and preserved the island in spite of a formidable army, which besieged it for the space of three months. But in 1522, it was attacked by Solyman II. with an army of 300,000 men, and taken by him, after having been in the possession of the knights 213 years.

After this loss, the grand master and knights retired first into the isle of Candia. Some time after pope Clement VII. gave them Viterbo. Lastly, Charles V. in 1525, gave them the island of Malta, which grant was confirmed by the pope in 1530: and hence they obtained the appellation of "knights of Malta;" though their proper name is that of "knights of the order of St. John of Jerusalem;" and their grand master among his other titles, still retains that of "master of the hospital of St. John," and "guardian of the poor of our Saviour Jesus Christ." The badge of the order is a "gold cross of eight points enamelled white, and worn by all the knights at their breast, pendant to a black ribbon." The knights of this order, whether novices or professed, when they go to war with the Turks, wear over their coats "a red jacket or tabard, charged both before and behind with a great full white cross, without points." See the preceding article.

The order of Malta have no other dominions besides their island, and some other little places in the neighbourhood, the chief whereof are Gozo and Comino.

The government is both monarchical and aristocratical, the grand master being the sovereign, and the chapter the senate. It is monarchical with regard to the inhabitants of Malta, and the isles adjacent, and even with regard to the knights in every thing relating to the statutes and rules of their

their order; and it is aristocratical with regard to the decision of any important affairs, which are not to be dispatched but by the grand master and the chapter. There are two councils; the one ordinary, composed of the grand master, as chief, and the grand crosses; the other complete, consisting of the grand master, the grand crosses, and the two senior knights of each language.

By the languages of Malta are meant the several nations of which the order is composed. Of these, authors have reckoned eight, *viz.* Provence, Auvergne, France, Italy, Arragon, Germany, Castile, and England.

The pillar (as he has been called) of the language of Provence is the grand commander of the order; he of Auvergne the grand marshal; he of France the grand hospitaler; he of Italy the grand admiral; he of Arragon grand conservator, or draper, as he was anciently called: the pillar of the language of Germany is grand bailiff; and he of Castile grand chancellor; the language of England, which has been extinct since the time of the Reformation under king Henry VIII. had for its pillar or chief, the grand turcopolier, or colonel of the cavalry. The language of Provence is the first, on account of Gerhard, a native of Provence, or of Raimond du Puy, their first grand master, who was a Provençal.

In each language there are several grand priories, and capital bailliages. To each language belongs a hall, where the knights eat, and hold their ordinary assemblies. Each grand prior has a number of commanderies.

The commanderies are either magisterial, or else by right, or, finally, by favour. The magisterial are those annexed to the grand mastership, of which there is one in each grand priory: commanderies by right are those which come by right of seniority; their seniority is computed from the time of their admission; but they must first have lived five years at Malta, and have made four caravannes, or cruising voyages, on the Turks and Corsairs: commanderies by favour are those which the grand master, or the grand prior, have a right of conferring; one of these they confer every five years on whom they please. The noble knights are called knights by right; and none but these can be bailiffs, grand priors, or grand masters. Knights by favour are those who, not being noble of themselves, are raised on account of some great exploit, or some notable service, into the rank of nobles.

The servitors, or serving-brothers, are of two kinds: 1. The servitors of war, whose functions are the same with those of the knights. 2. The servitors of religion, whose whole business is to sing the praises of God in the conventual church, and to officiate each in his turn as chaplain on board the vessels and galleys of the order.

The brothers of obedience are priests, who, without being obliged to go to Malta, take the habit of the order, make the vows, and attach themselves to the service of some of the churches of the order, under the command of a grand prior, or commander, to whom they pay obedience.

The knights of majority are those who, according to the statutes, are admitted at sixteen years of age. The knights of minority are those who are admitted from the time of their birth; which, however, cannot be done, without a dispensation from the pope.

The chaplains can only be admitted regularly from ten to fifteen years of age; after fifteen they must have a brief from the pope; till fifteen, the grand master's letter is sufficient. These are called *diacos*, and must give proof of their being born of creditable families.

For the proofs of nobility to be made before the admission of knights, in the language of Germany, they go back

six generations; in the rest, it is sufficient to go back to the great grandfather on the father's or mother's side.

There are also female hospitalers of the order of St. John of Jerusalem, sometimes also called *chevalieres*, or *sbe-knights*, whose business was to take care of the women-pilgrims, in an hospital apart from that of the men. This order was instituted in the year 1107, by Agnes, abbess of the hospital of St. Mary Magdalene, who, with her companions, made profession of the same rule, took the same habit, and bound themselves to observe the same vows, as Gerhard de Didier had done in the year 1099. The badge of this order was the same with that of the knights of Malta.

Since treaties of alliance between Christian and Infidel powers are now as common as between Christian powers alone; and since the Barbary Corsairs are less formidable and injurious to commerce than they were formerly, the order of Malta, notwithstanding its claim to the gratitude of European powers for a long, long series of past services, seems to have declined in importance and estimation.

Under the grand mastership of Rohan, indeed, the possessions belonging to the order of St. Anthony were added to those of Malta; several commanderies, situated in Poland, were restored; and a new language was installed, the Anglo-Bavarian; to which was afterwards united the grand priory of Russia, created by the emperor Paul, who, enamoured of chivalrous exploits, and well aware of the commercial and political advantages which Russia would derive from the possession of Malta, assumed the title of protector of the order, and was invested, together with the whole imperial family, with the grand cross of Malta.

Nevertheless, the European powers were very indifferent as to the independence of the order.

That the legislative assembly of France should pass a decree, annulling the order of Malta, was not matter of surprise: it was the natural consequence of a previous law, that every Frenchman, who was a member of any order of knighthood which required proofs of nobility, should no longer be regarded as a French citizen. Nor can it be matter of surprise that, by the same decree (Sept. 19, 1792), all its property should be annexed to the demesnes of France. The original hospitalers, and the first knights were Frenchmen; out of the eight languages France had three, besides commanderies situated in Alsace, Roussillon, and French Navarre, which were all dependencies of the two languages of Germany and Arragon. The confiscation of all this property was quite consonant with the prevailing atrocious system of revolutionary policy and morals. The enormous deficit which this plunder occasioned, ought to have excited the compassion, if it had not called forth the generosity, of other states; instead of which we find the order assailed to support the coalition against France. Thus, between two armies, the knights of Malta bear the blows of both! The Spanish and Portuguese commanderies, which had never before paid any taxes to their respective governments, were now called upon for a tenth of their revenue; those in the kingdom of Naples and in Sicily were subjected to heavier ones; and the order was treated still worse in Piedmont, where part of the property of the knights of Malta was ordered to be sold.

The revenue of the order in the year 1788 amounted to 3,156,719 French livres, and the expenditure to 2,967,503, leaving a surplus of 189,216. To the confiscation of its property in France, yielding an annual revenue of 1,392,974 livres, and its taxation by different sovereigns in support of the war against France, must be added the enormous loss which the treasury sustained by the depreciation of paper money, when it became necessary to realize the revenues

due from Spain and part of Italy. The left bank of the Rhine being ceded to the French by the treaty of Campo Formio, the order was deprived of all its property in these four new departments; and the different new republics, formed on every side, successively robbed it of what it possessed in Helvetia, and the Ligurian and Cisalpine republics. Malta, by these accumulated losses, was deprived of two-thirds of its revenue. It was compelled to borrow to the amount of six millions of livres; and at last its credit was fallen so low, that no one could be found to advance more. In the year 1796, the plate belonging to the men of war and to the galleys was melted down, and coined into money, as was also part of the grand master's, together with some of that employed for the use of the sick in the hospital. It was very evident, therefore, that this noble order, which for seven hundred years had been the terror of infidels and the bulwark of Christendom, was no longer held in that estimation and respect by the European potentates, which the remembrance of its valorous achievements might have been expected to inspire. Russia, under Paul I., certainly manifested a desire to afford Malta relief; the order also expected the payment of about a hundred thousand crowns from Spain, which most unfortunately did not arrive till a few days after the French had landed in the island, and which, of course, became a prey to them.

Notwithstanding the low state of the finances, Malta, at the time the French fleet made its appearance, was perfectly able to have made a formidable resistance against any attempt at landing; and if a landing had been effected, a still more powerful defence of the city Valetta. "Never to reckon the number of the enemy" made a part of the oath of every knight, on his admission into the order; and "to die at his post was a first principle of honour." The bulwarks of the island were master-pieces of fortification, and if the knights and the Maltese had been as faithful to themselves and to each other as at the siege by Solymán, Bonaparte would have retired from this rock of resistance abashed, confounded, and defeated. The treacherous surrender of the island gives an ample verification to the statement of the Maltese deputies: "The defection," say they, "and treason of which the order was guilty, will form an epoch in the annals of the world as striking as that by which we are again thrown under its despotic dominion, after it had abandoned us to an army unfaithful to all its promises and engagements."—"No one is ignorant that the plan of the invasion of Malta was projected in Paris, and confided to the principal knights of the order, resident at Malta. Letters in cyphers were incessantly passing and re-passing, without, however, alarming the suspicions of the deceased grand master de Rohan, or of the grand-master Hompesch." On the evening of the 9th of June, 1798, the French landed their troops at Magdalen creek, and on their approach "one single cannon shot" was fired from fort St. George! At day-break their shallops were seen advancing towards seven different points, Gozo, Cumino, La Malleha, Salmon, St. George, St. Julian, and La Trombrella, none of which made any resistance, except Gozo, which was attacked by general Regnier, and defended by the commander de Megriny. A dreadful scene of slaughter ensued: the Maltese people fought with a two-edged sword; they attacked the invaders with valour, and slew, without discrimination, the knights of the order, by whose treachery they had been suffered to effect a landing. That some among the Maltese were deluded by the promises universally lavished by the French, of liberty, equality, &c. cannot be doubted; but by their subsequent conduct it is fully proved, that the bulk of the people were most determinedly hostile to the

admission of the French, and that their detestation of the order was inexpressibly increased by a detection of its treachery on this occasion. When Bonaparte set sail, some of the knights actually enlisted under his banners!

It is unnecessary to give an account of the conduct of the French on their possession of Malta: every thing in the public buildings, "which bore the stamp of nobility, or recalled to mind the celebrated exploits performed by illustrious chiefs, was broken and destroyed." The arms of the order, together with those of the principal chiefs, were effaced not only in the principal inns, but in the palace of the grand master, himself being present on the occasion! The knights who were not in the French interest, were ordered to quit the island in three days, and a disgraceful salary was voted to Hompesch, as an equivalent for the property annexed to the grand mastership. The knights who were attached to the French interest had but little reason to applaud the wisdom of their political speculations: exposed to the rage of the Maltese, and unprotected by their new friends, they were shut up in different fortresses, some fled, some absolutely perished from want, and all were despised and hated.

They who remained faithful to their duty were scattered in different places. Hompesch retired to Trieste, separated himself from the companions of his flight, and resigned the office of grand master, which he had so ingloriously filled. Many retired to the dominions of the emperor of Russia, who took upon himself the title of grand master, and created a new Russian priory for the benefit of the nobles in his dominions, who followed the rites of the Greek church.

Notwithstanding the flight of Hompesch, and the knights who accompanied him, and notwithstanding the treachery of those apostate members of the order who remained behind, attached to the provisional government established in the island by the French, the brave inhabitants rose in arms against their invaders, who were shut up within the gates of Valetta, without daring to issue forth and face the terrible vengeance of the people. The blockade of Malta by the English lasted two years; namely, from September 2, 1798, to September 4, 1800, when the city surrendered. The situation of the city was so deplorable from the alarming mortality among the troops and inhabitants, arising doubtless from the scarcity of provisions, that a surrender appeared absolutely certain. In September, 1799, a fowl, which before the blockade, used to sell for 6*d.* sold for from 2*l.* 3*s.* to 2*l.* 10*s.* English; a pigeon was worth 10*s.*; a rabbit about the same; a *rat* from 1*s.* to 1*s.* 6*d.*; fresh pork sold for 7*s.* a pound, and cheese for the same. The flesh of mules and asses was in such request, that the people complained bitterly whenever they were deprived of it. The French, however, raised vegetables, bred poultry, rabbits, &c.; and, under the vigilance and unceasing encouragement of their general Vaubois, contrived, as much as possible, to relieve their wants and support their spirits. The garrison was put upon half-pay in the month of August; in the following December it was entirely stopped, as was their allowance of wine and brandy. To the honour of the French troops, for it is impossible to contemplate such conduct without admiration, not a murmur was heard, and during a whole twelve-month there were scarcely twenty deserters, and the greatest of these were either volunteers or sailors! The situation of the inhabitants now became every day more and more disastrous; and such were the effects of poverty, disease, and frequent emigration, that of 40,000 souls in September 1798, there only remained 13,000 in 1799: these were reduced to 10,000 in the following October, and to 7500 in March 1800. In the last

period of the blockade provisions rose to an incredible price : a bottle of oil fold for a guinea, a pound of coffee for 2*l.* 8*s.* and a pound of sugar for a few shillings less ; asses, mules, horses, dogs, and cats, were almost all consumed ; and general Vaubois was at last compelled, by famine, to propose terms of capitulation. He received from the English such as were due to so persevering and courageous a resistance, and such at the same time as proved that Britons pay just homage to the bravery of an enemy. The native Maltese were the only party who had reason to complain of the capitulation, and still greater of the treaty of Amiens, which again consigned them to the order which had given such irrefragable proofs of cowardice and treachery.

By the treaty of peace between Great Britain and the French republic, concluded at Amiens 27th March 1802, it was stipulated, that the islands of Malta, Gozo, and Cumino, should be restored to the order of St. John of Jerusalem, to be held on the same conditions on which it possessed them before the war, and under the following stipulations. 1. The knights of the order, whose languages shall continue to subsist after the exchange of the ratification of the present treaty, are invited to return to Malta as soon as the exchange shall have taken place. They will there form a general chapter, and proceed to the election of a grand master, chosen from among the natives of the nation which preserve their language, *i. e.* a right of election, as belonging to a particular Catholic nation, unless that election has been already made since the exchange of the preliminaries. It is understood that an election made subsequent to that epoch, shall alone be considered valid, to the exclusion of any other that may have taken place at any period prior to that epoch. 2. The governments of the French republic, and of Great Britain, desirous to place the island and order of Malta in a state of entire independence with respect to them, agree that there shall not in future be either a French or English language, and that no individual belonging to either the one or the other of these powers shall be admitted into the order. 3. There shall be established a Maltese language which shall be supported by the territorial revenues and commercial duties of the island. This language shall have its peculiar dignities, an establishment, and an hotel. Proofs of nobility shall not be necessary for the admission of knights of this language ; and they shall be moreover admissible into all offices, and shall enjoy all privileges, in the same manner as the knights of other languages. At least half of the municipal administration, civil, judicial, and other employments depending on the government, shall be filled by inhabitants of the islands of Malta, Gozo, and Cumino. 4. The forces of his Britannic majesty shall evacuate the island and its dependencies, within three months from the exchange of the ratifications, or sooner if possible. At that epoch it shall be given up to the order in its present state, provided the grand master or commissaries, fully authorized according to the statutes of the order, shall be in the island to take possession ; and that the force which is to be provided by his Sicilian majesty, as is hereafter stipulated, shall have arrived there. 5. One-half of the garrison at least shall be always composed of native Maltese ; for the remainder the order may levy recruits in those countries only which continue to possess the languages. The Maltese troops shall have Maltese officers. The command in chief of the garrison, as well as the nomination of the officers, shall pertain to the grand master ; and this right he cannot resign, even temporally, except in favour of a knight, and in concurrence with the advice of the council of the order. 6. The independence of the isles of Malta, Gozo, and Cumino, as well as the present arrangement, shall be placed under the protection and guarantee of France,

Great Britain, Austria, Spain, Russia, and Prussia. 7. The neutrality of the order, and of the island of Malta, with its dependencies, is proclaimed. 8. The ports of Malta shall be opened to the commerce and navigation of all nations, who shall there pay equal and moderate duties ; those duties shall be applied to the cultivation of the Maltese language, as specified in paragraph 3 ; to that of the civil and military establishments of the island ; as well as to that of a general lazaretto, open to all ensigns. 9. The states of Barbary are excepted from the conditions of the preceding paragraphs, until, by means of an arrangement to be procured by the contracting parties, the system of hostilities which subsists between the states of Barbary and the order of St. John, or the powers possessing the languages, or concurring in the composition of the order, shall have ceased. 10. The order shall be governed, both with respect to spirituals and temporals, by the same statutes which were in force when the knights left the isle, as far as the present treaty shall not derogate from them. 11. The regulations contained in the paragraphs 3, 5, 7, 8 and 10. shall be converted into laws and perpetual statutes of the order, in the customary manner ; and the grand master (or if he shall not be in the island at the time of its restoration to the order, his representative), as well as his successors, shall be bound to take an oath for their punctual observance. 12. His Sicilian majesty shall be invited to furnish 2000 men, natives of his states, to serve in garrison of the different fortresses of the said islands. That force shall remain one year, to bear date from the restitution of the knights ; and if, at the expiration of this term, the order should not have raised a force sufficient, in the judgment of the guaranteeing powers, to garrison the island and its dependencies, such as is specified in the paragraph, the Neapolitan troops shall continue there until they shall be replaced by a force deemed sufficient by the said powers. 13. The different powers designated in the sixth paragraph, *viz.* France, Great Britain, Austria, Spain, Russia, and Prussia, shall be invited to accede to the present stipulations.

The Maltese remonstrated in spirited and indignant terms against that portion of the treaty of Amiens which consigned their island to the order : and demanded that it might be restored to them ; or that the expences they had incurred might be paid to them, or that they might be indemnified for the losses occasioned by the war, and by the plunder of the French. They then contest the title of the knights to the possession of the island, and placing, as they state their case, a full reliance in the sincerity of the British government, and in the faith of the British nation, the Maltese were more desirous of becoming subjects of the king of England, and of enjoying all the advantages of free subjects of a monarch, who is the father of all his people, than to assert and maintain their own independence ; but never did they suspect, nor can they now for a moment believe, that, violating all the laws of justice, divine and human, they are to be forcibly delivered up by their auxiliary allies, as a conquered people, or as vile slaves sold for a political consideration to other masters, to masters, " whose tyranny, extortion, and sacrilege, have rendered them the execration of every virtuous mind, and to whom, whatever horrible calamity may ensue, the Maltese nation will never submit." The representation proceeds to assert, that if the island were again delivered up to the order, it would virtually be in the hands of the French, since they are not (even including those of the new Anglo-Bavarian language), more than a *tertium* part of the knights who are not at the blind disposal of France. Indignantly is it observed, " if the knights of the order, in possession of an independent sovereignty and revenue, enjoying every ease and pleasure that imagination can form, engaged in objects

of luxury, careſſed and revered as ſo many ſovereigns; if in this condition the French could command them to quit their terreſtrial paradise, to wander in the wide world, and could induce them to become partisans of their cauſe, what muſt not the power of the ſame French over them be, dependent, degraded, diſhonoured, reduced to beggary, in whom is extinct every ſpark of honour, and who have been guilty of the blackeſt, the moſt horrible infidelity, apoſtacy towards their God, and violation of the ſacramental ordinances?"—"With reſpect to the guarantee of this or that power, but too well is our iſland acquainted with the French and the order, not to be convinced of the fallibility of ſuch a propoſition. The firſt war, whether of length or ſhort duration, puts an end to it entirely. If ever a third power were to occupy ſome parts of the fortrefſes, the troops would be corrupted by French money and French principles; and immense are the ſums that would be expended for that purpoſe. The military poſts are dependent one upon the other. We are able to point out," ſay the representatives, "the utter impoſſibility of occupying a part, without the whole. We can clearly demonſtrate how they can, and will obtain their ſeveral ends. We can make it evident, that there is no ſecurity for the inhabitants, unleſs Britiſh troops are placed in poſſeſſion of all the fortrefſes, and unleſs the adminiſtration of juſtice is placed in the hands of a Britiſh civil government." Boifgelin's Anc. and Mod. Malta.

MALTA, or *Medina*. See *CIVITA Vecchia*, and MALTA, *ſupra*.

MALTA Earth, in the *Materia Medica*. See MELITENSIS terra.

MALTEPEC, in *Geography*, a town of Mexico, in the province of Mechoacan; 60 miles E.S.E. of Mechoacan.

MALTESE, in *Biography*. The proper name, the birth-place, and the education of the ingenious painter who bears this appellation, are alike unknown; but his works, which conſiſt chiefly of objects in ſtill life, are valued for their exhibition of freedom, boldneſs, and truth. They are generally compoſed of fruit, carpets, jewellery, ſhells, tapeſtries, &c. to which, by a judicious management in their compoſition, a brilliant colour, and a ready and powerful touch, he produced a ſtrong and brilliant relief; and often a moſt enchanting effect of chiaro-oscuro.

MALTHA, Μαλθα, in *Antiquity*, denotes any cement, or glutinous body, which has the faculty of binding things together. See *Calcareous CEMENT*.

Ancient writers make mention of divers forts of maltha, native and factitious; one of the latter much in uſe was compoſed of pitch, wax, plaſter, and greaſe.

Another kind, with which the Romans plattered and whitened the inſides of their aqueducts, was made of lime ſlaked in wine, incorporated with melted pitch, and freſh figs.

Natural maltha is a kind of bitumen, called "mineral pitch," with which the Aſiatics platter their walls. When this is once ſet on fire, water will not quench it; but ſerves rather to make it burn more fiercely. See BITUMEN.

MALTHA, in *Ichthyology*, the name of a voracious fiſh of the ſhark kind, called the *ſerrat*, and the *lamiola* by ſome authors, a diminutive of *lamia*, ſignifying a ſmall ſhark. Its teeth are broad and pointed, like thoſe of the ſhark; the fiſh has alſo many rows of theſe; the noſe is ſhort, and its fleſh lax and ſoft. See SQUALUS.

MALTHOCODE, a term by which the Greek writers expreſs the emollient topical remedies prepared with oil. Hippocrates expreſſly forbids the uſe of theſe in old ulcers.

MALTON, or NEW MALTON, in *Geography*, a borough and market-town in the wapentake of Ryedale, North

Riding of the county of York, England, is ſituated 18 miles diſtant from York, and 217 from London, on an eminence overlooking the river Derwent, which runs through a beautiful vale on the ſouth-eaſt ſide of the town. Malton was of ſome note in the Saxon times. Immediately before the Norman conqueſt, it was poſſeſſed by a nobleman named Colebrand, from whom it was taken by the Conqueror, who gave it to Gilbert Tyſon, one of his followers. In the reign of Henry I., Euface St. John poſſeſſed this lordſhip by inheritance from his mother, who was grand-daughter and heiress of Gilbert Tyſon. In the conteſt between the emperors Maud and king Stephen, the town was reduced to aſhes. It was rebuilt by Euface, and then acquired the name of New Malton. In the reign of James I., Ralph, lord Eure, who was then in poſſeſſion of the manor, built a magnificent houſe here; but leaving no iſſue, his eſtates came to his uncle William, lord Eure, who left two daughters, co-heireſſes. Theſe diſagreeing about this noble manſion, it was, after a tedious and expenſive litigation, determined that it ſhould be pulled down, and its materials divid-d: and ſo ſcrupuloſly was the diſiſion made, that the "ſtones even were ſhared one by one." But it ſeems that ſome compromise took place before the dilapidation was completed, as the lodge in the front, with three arched gateways, are yet ſtanding. The manor was afterwards conveyed to ſir Thomas Wentworth, and from him deſcended to Thomas, marquis of Rockingham, who was ſucceeded in titles and eſtates by his ſon Charles, the late marquis; after whoſe death, the eſtates devolved on his nephew, earl Fitzwilliam.

Malton is about half a mile in length from eaſt to weſt. The entrance at the eaſt end is by a ſpacious ſtone-bridge over the Derwent, whence the principal ſtreet riſes with a continued, but gentle aſcent through the town. The houſes are moſtly built of ſtone; and in the year 1801 were in number, according to the population ſurvey, 604, and were occupied by 3047 perſons. The town comprizes two pariſhes, St. Michael's and St. Leonard's; each having its reſpective church: the ſpire of the latter has a ſingular appearance. Malton is a borough by preſcription, and has ſent two members to parliament ever ſince the 23d year of Edward I.; the right of election being veſted in the holders of about 100 burgage tenures. The town is governed by a bailiff. Markets are held on Tueſdays and Saturdays; and a brisk trade is carried on in corn, of which a great quantity is ſent into the weſtern parts of Yorkſhire, and to ſeveral other places. The Derwent is navigable to Malton, where the quantity of corn ſhipped in the year 1796 amounted to 56,065 quarters. Here are three annual fairs, which exhibit a great ſhow of horſes and cattle, and are much frequented by farmers, graziers, and horſe-dealers. Hinderwell's *Hiſtory of Scarborough*. *Beauties of England and Wales*, vol. xvi. by John Bigland.

MALTOY, a town of Hindooſtan, in Goondwana; 60 miles N.W. of Nagpour. N. lat. 21° 45'. E. long. 78° 58'.

MALTRA, a town of Sweden, in Angermland; 42 miles N.N.W. of Hernofand.

MALVA, in *Botany*, is thought by Ambroſinus to have obtained its name from *mollis*, alluding to the ſoothing or emollient qualities with which it is endued. The ancients reckoned it an excellent ſtomachic, frequently mixing it with *Lactuca* in their fallads. Its Greek name *μαλαχνη* is of ſimilar origin, being derived from *μαλασσειν*, *to ſoften*. Horace, as every body knows, ſpeaks of "*levet malva*," apparently meaning light of digeſtion; and Martial ſays, "*Utere lactucis, et mollibus utere malvis*." Linn. *Gen.* 354. Schreb. 466. Willd. *Sp. Pl.* v. 3. 774. Mart.

Mill. Dict. v. 3. Sm. Fl. Brit. 740. Ait. Hort. Kew. ed. 1. v. 2. 446. Juss. 272. Lamarck Illustr. t. 582. Gærtn. t. 136.—Clafs and order, *Monadelphia Polyandria*. Nat. Ord. *Columniferæ*, Linn. *Malvaceæ*, Juss.

Gen. Ch. *Cal.* Perianth double, inferior; the outer generally narrower, of three ovate or heart-shaped, acute, permanent leaves; the inner of one leaf, five-cleft half way down, larger, broader, permanent. *Cor.* Petals five, obcordate, abrupt, flat, fixed by their base to the tube of the stamens. *Stam.* Filaments numerous, united below into a tube, separate and loose at the top, and along the surface; anthers kidney-shaped. *Pist.* Germen superior, orbiculate, depressed; style cylindrical, short; stigmas many, bristly, as long as the style. *Peric.* Capsule roundish, composed of the same number of two-valved cells as there are stigmas, placed in a whorl about a columnar receptacle; finally deciduous. *Seeds* solitary, occasionally two or three, kidney-shaped.

Eff. Ch. Calyx double; the outermost of three leaves. Capsules numerous, circularly arranged. Seeds mostly solitary.

Obf. Schreber remarks that some species have only two leaves to the outer calyx, and that in *M. caroliniana* each capsule is divided into two cells by a transverse membrane.

This extensive genus furnishes many ornamental plants, though chiefly of exotic growth. We select the following species to illustrate its history. Linnæus has defined only twenty-six in the 14th edition of his *Systema Vegetabilium*. Professor Martyn however has thirty-four, and Willdenow describes fifty-five. They are arranged under two sections, namely, such as have undivided leaves, and such as have angular leaves, all our three native Mallows belonging to the latter section.

Sect. 1. *Leaves undivided.*

M. spicata. Spiked Mallow. Linn. Sp. Pl. 967. (*Althæa spicata*, betonicæ folio villosissimo; Sloan. Jam. v. 1. 219. t. 138. f. 1.)—Leaves ovate or heart-shaped, notched, downy. Spikes oblong, hairy.—A native of barren, rocky lands in Jamaica, flowering in September and October. *Stem* two or three feet high, pale green, branched. *Leaves* roundish, on footstalks, pale green and smooth. *Flowers* in spikes at the summits of the twigs and branches, orange-coloured.

M. scoparia. Small yellow-flowered upright Mallow. Willd. n. 4. L'Herit. Stirp. t. 27. Jacq. Ic. Rar. t. 139.—Leaves ovate, notched or serrated. Flowers axillary, crowded together. *Stem* shrubby.—A native of Peru, discovered near Lima by Dombey, flowering late in the summer. The inhabitants of Spanish America make brooms of its branches, whence the specific name. *Stem* about six feet high, upright, round, smoothish, much branched. *Leaves* rather drooping, somewhat heart-shaped, acute, entire at the base, downy, rugged, pale green. *Flowers* on short stalks, of a yellow colour spotted with red.

Sect. 2. *Leaves angular.*

M. sylvestris. Common Mallow. Linn. Sp. Pl. 969. Engl. Bot. t. 671. Curt. Lond. fasc. 2. t. 51. Woodv. Med. Bot. t. 54.—*Stem* upright, herbaceous. Leaves with seven sharpish lobes. *Leaf-stalks* and *flower-stalks* hairy.—By hedges and paths both in cultivated and waste ground all over England, flowering from May to September.—*Root* perennial, spindle-shaped, branched, whitish. *Stem* generally erect, branched, round, hairy, many-flowered. *Leaves* alternate, on footstalks, heart-shaped, folded, seven-lobed, roughish, notched; the upper ones nearly palmate. *Stalks* crowded together, hairy, single-flowered. *Flowers* reddish-purple or lilac-coloured, veined with a deeper tinge; petals

obcordate, thrice as long as the calyx, which is hispid. "The whole herb," says Dr. Smith, "especially the root, abounds with a pure mucilage, and possesses the emollient qualities of the Marsh Mallow, *Althæa*, though perhaps in an inferior degree. It has, however, the advantage of being much more common, and within every body's reach."

M. rotundifolia. Dwarf Mallow. Linn. Sp. Pl. 969. Engl. Bot. t. 1092. Curt. Lond. fasc. 3. t. 43.—*Stems* prostrate. Leaves roundish heart-shaped, five-lobed. *Fruit-stalks* bent downwards.—Common in waste ground, flowering copiously from June to September. *Root* annual, branched, whitish, mucilaginous. *Stems* numerous, prostrate, almost simple. *Leaves* smaller than in *sylvestris*, five or seven-lobed. *Flowers* flesh-coloured. A variety of this is sometimes found with smaller petals, indeed not longer than the calyx. This was considered as a distinct species by Mr. Hudson, who called it *parviflora*, and Dr. Smith figured it in Engl. Bot. t. 241, under the name of *pusilla*, but he afterwards was satisfied of its being a mere variety of *M. rotundifolia*.

M. moschata. Musk Mallow. Linn. Sp. Pl. 971. Engl. Bot. t. 754. Curt. Lond. fasc. 4. t. 50.—*Radical* leaves kidney-shaped, cut; those on the stem in five deep pinnatifid and finely divided segments. Calyx hairy.—Not uncommon by the sides of fields and roads in a gravelly soil, flowering in July and August. *Root* perennial, somewhat woody, tenacious. *Stems* erect, rather branched. *Lower leaves* heart or kidney-shaped, lobed; *upper* divided to the base into five segments, which are deeply pinnatifid, cut and channelled. *Flowers* large, handsome, rose-coloured. The whole herb gives out a strong, musky odour, which is scarcely perceptible, however, in cold or damp weather.

M. Alcea, was once reckoned a British species, and Willdenow still mentions it as such, but without reason. Some variety of *moschata*, with broader leaves than usual, is supposed to have been taken for it.

MALVA, in *Gardening*, comprehends plants of the herbaceous, annual, biennial, perennial, and shrubby kinds, of which the species cultivated are, the spiked mallow (*M. spicata*); the American mallow (*M. americana*); the Peruvian mallow (*M. peruviana*); the creeping mallow (*M. caroliniana*); the oriental mallow (*M. orientalis*); the whorl-flowered mallow (*M. verticillata*); the curled mallow (*M. crispa*); the palmated mallow (*M. egyptia*); the vervain mallow (*M. alcea*); the musk mallow (*M. moschata*); and the gooseberry-leaved or cape mallow (*M. capensis*).

In the last or Cape species, there are varieties in which the stems are thicker and higher, of a brownish-red colour; the leaves hirsute, broader, with wider segments, less deeply cut, but with the toothlets sharper and serrate; the whorls of fruit a little larger, and not muricated, and in which the hairs of the leaves and stem are simple, not compound; the flowers almost upright, not drooping or bending downwards.

Method of Culture.—It may be observed that the ten first sorts are all capable of being raised from seeds, which, in the hardy kinds, should be sown in the situations where the plants are to grow, in patches of four or five in each, in the spring or beginning of autumn, covering them to the depth of half an inch. They may likewise be sown upon a bed of fine earth, and be afterwards removed to the places where they are to flower. Those which are natives of hot climates should be sown in pots, and plunged in a hot-bed.

In the two latter modes, when the plants have attained some growth, they should be removed into their proper situations, or into other pots, to be afterwards managed according to the difference of the kinds.

And

And the last fort and varieties may be raised also by seed, which should be sown upon a hot-bed, or in pots, and plunged in it. When the plants have attained some growth, they should be removed into separate pots, replunging them in the hot-bed till fresh rooted, when they should be gradually inured to the full air, managing them afterwards in the same manner as other exotics of the green-house kind.

The hardy forts afford a pleasing variety in the shrubbery and other parts, while those of the more tender and shrubby kind produce a good effect in the green-house, and among potted collections in other places.

MALVA *Arborea*, in *Botany*. See HIBISCUS and LAVATERA.

MALVA *Rosea*. See ALCEA and HIBISCUS.

MALVA *Sylvestris*. *Common Mallow*, in the *Materia Medica*, has a strong affinity to the althæa or marsh mallow, both in a botanical and in a medicinal respect; but the roots of the malva are useless, while those of althæa are of greater efficacy than any other part of the plant. Accordingly we find, that only the leaves and the flowers of the former are directed by the college for pharmaceutical purposes. Formerly the malva was admitted among the more common articles of diet. To this purpose it is referred to by Horace, l. i. od. 31.

“ ——— Me pascunt olivæ
Me cichorea leveſque malvæ.”

The Chinese are said to eat the leaves of mallow, either raw as salad, or boiled as spinach. As to the medicinal qualities of this plant, we shall refer to the article ALTHÆA; observing, that the leaves afford a similar glutinous juice, which is fitted to answer the same purposes as those of marsh-mallow, and are therefore principally used in fomentations, cataplasms, and emollient enemas; but the internal use of these leaves seems to be wholly superseded by the radix althææ. Cicero (Epist. lib. vii. ep. 26.) mentions the laxative quality of this plant. Woodv. Med. Bot.

MALVA, in *Ancient Geography*, a large and deep river of Africa, in Mauritania Cæsariensis, which runs into the Mediterranean.

MALVACEÆ, in *Botany*, a natural order of plants, the 74th in Jussieu's system, or the 14th of his 13th class, equivalent to the *Columnifera* of Linnæus, which article the reader will find in its proper place.

MALVANA, in *Geography*, a town of the island of Ceylon; 12 miles E. of Columbo.

MALVASIA, a town of European Turkey, situated on a promontory, almost surrounded by the sea, on the eastern coast of the Morea: its harbour is good, but not large. It is the see of a Greek archbishop, and one of the strongest towns in the Morea: the territory belonging to it is about three miles in circuit, and furnishes, in part, those celebrated vines, from which was obtained the wine, formerly much valued, under the name of Malmsey. This was formerly a place of great resort for the worship of Esculapius, which was brought hither by the inhabitants of *Epidaurus* (which see). This place is called by the Turks “Menevtsche;” and it is distant about a league from the ruins of *EPIDAUROS Limeræ* (which see), and 40 miles E.S.E. of Mistra. N. lat. 36° 52'. E. long. 23° 4'.

MALVAVISCUS, in *Botany*, so called by Dillenius in his *Hortus Elthamensis*, v. 2. 210. t. 170. f. 208. Linnæus however considered it as a species of *Hibiscus*, and gave it the name of *H. Malvaviscus*, Linn. Sp. Pl. 978. It is now the *Achania* of Banks and Solander, and is characterized by a convoluted corolla, ten stigmas, and a pulpy fruit. (See HIBISCUS and ACHANIA.) *Malvaviscus* of Gartner, t. 135, is *Hibiscus populneus* of Linnæus, certainly a distinct genus from *Hibiscus*, but the name is untenable.

MALUCA, in *Geography*, a town of Peru, in the diocese of Truxillo, on the coast; 45 miles N. of Payta. S. lat. 4° 25'.

MALVENTRA, a small island near the west coast of Sardinia.

MALVERN, GREAT, a village and parish in the lower division of the hundred of Pershore, and county of Worcester, England, is situated on the eastern declivity of the Malvern hills, at the distance of eight miles from Worcester, 24 from Cheltenham, and 120 from London. A hermitage, or religious society for seculars, was founded here in the time of Edward the Confessor, and obtained some endowment from that monarch. About the year 1083, Aldewine, the chief of this place, was persuaded by St. Wolstan, bishop of Worcester, to become a Benedictine monk: upon which he immediately set about procuring benefactions for building and maintaining a priory of that order. Gislebert, then abbot of Westminster, assigned several manors and estates to its support, whereby, with the munificence of devotees, the monastery was raised to great wealth and consequence. Few vestiges now remain, except the church, which, at the dissolution, was purchased by the inhabitants, and rendered parochial. This is still a magnificent structure, being 171 feet in length, and 63 in breadth, with an embattled and pinnacled tower, rising from the centre to the height of 124 feet. The painted glass in the windows, representing many scenes from Scripture history, was once the object of universal admiration; but, through time and neglect, is now in a mutilated state, though enough is left to afford an idea of its former beauty. Several parts of the choir are ornamented with tessellated pavement, exhibiting the arms of many ancient and noble families. The tombs and monumental inscriptions are very numerous, and some of them of remote antiquity: the inscription on Walcher, the second prior of Malvern, which was discovered in 1711, is dated 1135. Among the tombs is one of a Saxon knight, with his battle axe and other accoutrements, supposed to be the only one of this kind in England. Malvern has long been noted for two medicinal springs: that called St. Anne's well, about a quarter of a mile from the church, is bituminous, and esteemed very salutary; the other is chalybeate, but is in a great measure neglected. Great Malvern, according to the population return in the year 1810, contained 819 inhabitants.

About three miles distant is the hamlet of *Little Malvern*, which was once a considerable village, but now contains only six houses, inhabited by 34 persons. A Benedictine priory was founded here, in the year 1171, by two brothers, Joceline and Edred, who were successively priors. The church was rebuilt in 1482 by John Alcock, bishop of Worcester, but is now in a ruinous state.

MALVERN *Hills*, are situated in the counties of Worcester, Gloucester, and Hereford, but principally on the south-west part of the former, making a distinct boundary to the rich vale of the Severn, lying to the east, and standing as a frontier between Worcestershire and Herefordshire. This lofty range of hills occupies a space about nine miles in length from north to south, and from one to three miles in breadth. The highest parts are those called the Herefordshire and Worcestershire Beacons, about four miles distant from each other; the former rising to the height of 1280 feet, and the latter to 1313 feet above the surface of the Severn. On the Herefordshire Beacon are the remains of an ancient encampment, consisting of a double entrenchment; the outermost about half a mile in circumference.

The avenues and passes are still to be seen, and the greatest part is in fine preservation. The vestiges of another entrenchment, consisting only of a single ditch, appear about a mile and half further to the south; and on the declivity of the Beacon is a cave cut in the rock, about ten feet long, six broad, and seven high, of rude workmanship and unknown origin.

From the Malvern hills issue various springs, of different qualities, according to the substances they are impregnated with; but that which has for several ages been reputed of peculiar medicinal efficacy, and has obtained the name of the Holy-well, rises about half-way up the east side of a hill, nearly mid-way between Great and Little Malvern. The source of the spring is secured by a convenient erection, containing a bath and other accommodations. The district called Malvern-Chase contains about 8000 acres, chiefly in Worcestershire; only about 700 being in the two adjoining counties. Ruff's History of Cheltenham, 8vo. 1803. Shaw's Tour into the West of England, 8vo.

MALVERN Waters. See *MALVERN WATERS.*

MALVINDA, in *Botany*, Indian Mallow, a name of Dillenius for some species of the *Sida* of Linnæus. It is still more exceptional than *Malvarifcus*.

MALVISANO, in *Geography*, a town of Italy, in the Bressan; 13 miles S.S.E. of Brescia.

MALUNG, a town of Sweden, in Dalecarlia; 55 miles W. of Fahlun.

MALURA, in *Botany*, the Sanskrit name of the *Cratæva marmelos* of Linnæus. (See *CRATEVA*.) It is also called *bilwa* or *bilva* by the Hindoos, who reckoned it a sacred shrub and fruit especially dedicated to Siva, probably because the latter is of a conical form, cones being typical of Siva, as the personification of fire. Many superstitious practices, and apparently idle tales, are connected with this fruit, in the mythological usages and legends of the East Indies. Chaplets of *bilwa* flowers decorate the statues of Siva, but of no other deity, nor are they offered in sacrifices to any other. A pious Hindoo seeing any of these flowers fallen on the ground, would, it is said, reverently remove them to a temple of Siva. The Hindoo poets call it *Sriphul*, the flower of Sri, or Lakshmi, the goddess of abundance; who is fabled to have bestowed it on mankind, at the request of Ifwara, or Siva. (See *LAKSHMI*.) The fruit is warm, cathartic, of delicious taste, and exquisite fragrance, and of valuable aperient and detergent qualities. The mucus of its seed is used as a cement. See *Asiatic Researches*, vol. ii.

MALUS, the ancient Latin name of an apple-tree, derived from the Greek *μᾶλον*, is retained generically by Jusseu, Gen. 334, after Tournefort, t. 406, to distinguish the apple from the pear, merely because the fruit of the former is umbilicated at its base, and the styles united at their lower part. The latter character is the most material, and appears to be founded in truth; but surely these plants form one natural genus. See *PYRUS*.

MALUS Assyria, one of the many names given by the ancients to the citron; they also call it *malus Medica*, and by several other names, as these were expressive of the country whence they had the fruit. See *CITRUS* and *CITRÆ Mense*.

MALUS Americana. See *CACTUS*, *CRATEVA*, and *HIPPOCRATEVA*.

MALUS Armeniaca. See *PRUNUS*.

MALUS Aurantia. See *CITRUS*.

MALUS Indica. See *RIAMNUS Jujuba*.

MALUS Limonia. See *CITRUS*.

MALUS Persica. See *ACHRAS*, *AMYGDALUS*, and *MAMMISA*.

MALUS Punica. See *PUNICA Granatum*.

MALUTAYA, in *Geography*, a small island in the sea of Mindoro. N. lat. 11° 12'. E. long. 120° 52'.

MALWA, a province or soubah of Hindoostan, one of the most extensive, the most elevated, and highly diversified in Hindoostan; and belonging to the extensive empire of the Mahrattas. It is bounded on the N. by Agimere and Agra, on the E. by Allahabad, on the S. by Candeish, and on the W. by Guzerat. Ougein is the capital of one Mahratta prince, and Indore of another. It is now ruled in sovereignty by Dowlut Rao, nephew and successor of the late Madaji Sindiah. The noble river Narmada, or Nerbudah, washes it on the south, dividing it from the province of Candeish. The Chumbul on the N.W. divides it from Ajmeer and Guzerat. On the S.E. it joins the dominions of the raja of Berar, and on the N.E. the British territories under the government of Bengal. Malwa may be roundly estimated at about 350 miles in length, and nearly as much in breadth. This soubah is very temperate in respect of climate, its capital city, Ougein, nearly centrally situated, being just within the northern tropic. (See *OUGEIN*.) It is well watered, having, besides numberless lakes and smaller streams, the rivers Sibera, Kalisind, Neem, and Narmada flowing through it. It is an elevated region; and is very productive in grain and fruit, including wheat and grapes. Here are several noble cities and flourishing towns, of which Ougein, Gurrah Mandla, Chandery, Bopal, Manduah, Dhar, and Naderbar, may be reckoned the chief. In the Ayeen Akbery, Ougein is stated, on the personal knowledge of the author of that work, to have contained, when he visited it in 1596, 360 Hindoo temples. Chandery is described as having 14,000 stone houses, 384 markets, 360 caravanferais, and 12,000 mosques. Its military strength is also very highly rated. We take this occasion to correct a typographical error in the article *INDRA*, whence reference is made to this. About the middle of the second column of that article is a stop and break at the word *Malwa*, and a new article commenced with *INDRA Malwa*. These two words are to be struck out, and the lines will then run thus—“particularly Ujaini, or Oojein, the capital of Malwa; the hereditary possession of the family of Sindia.” For further particulars, see *MAHRATTAS*.

MALWALLY, an island in the East Indian sea, about 15 miles in circumference, containing two good harbours. N. lat. 7° 0'. E. long. 115° 20'.

MALZIEU, a town of France, in the department of the Lozere, and chief place of a canton, in the district of Marvejols; five miles N.N.E. of St. Chély. The place contains 1060, and the canton 5742 inhabitants, on a territory of 160 kilometres, in 10 communes.

MAMADEBAD, or *MAMED-ABAD*, a town of Hindoostan, inhabited by Banians, who carry on a considerable traffic in thread and cotton.

MAMADISCH, a town of Russia, in the government of Kazan, on the Viatka; 16 miles N.E. of Kazan. N. lat. 56° 26'. E. long. 50° 30'.

MAMAK, a sea-port town of Abascia, on the Black sea; 110 miles W. of Ifgaur. N. lat. 43° 26'. E. long. 38° 25'.

MAMA-KATING, a township of America, in Ulster county, New York, on Delaware river; containing 1631 inhabitants.

MAMAKATUN, a town of Turkish Armenia, on the Euphrates; 12 miles N. of Arzingan.

MAMA-

MAMALEGERY, a town of Hindoostan, on the confines of Dindigul; 60 miles E. of Cochin.

MAMALAKJE, one of the Calaur islands. S. lat. $6^{\circ} 40'$. E. long. $123^{\circ} 33'$.—Also, a cluster of small islands extending about 60 miles in length from N.W. to S.E. and 30 in breadth, in S. lat. $6^{\circ} 50'$. E. long. 121° .

MAMALUKES, **MAMMELUKES**, *Mammalucks*, or *Mamlouks*, the name of a dynasty, which reigned a considerable time in Egypt.

The word comes from מלך, *regere, imperare*, the Arabic participle of which is מלך, *Mamluc*, which signifies *subject*, or one under the dominion of another. Scaliger holds, that the word is Arabic, and that it properly signifies something bought with money; but others will have it signify any thing acquired or possessed either as prize or purchase; and this gives the sense of *slave*.

The Mamlouks, or Mamlouks, were originally Turkish and Circassian slaves, who were introduced into Egypt, in consequence of an expedition which took place in the year 1227. The Moguls, sword in hand, pillaging, burning, and murdering, without distinction either of age or sex, reduced the whole country of Sihoun, quite to the Tigris, to a heap of ashes; and passing to the north of the Caspian sea, extended their ravages even into Russia and the Cuban. The Tartars, weary of massacring, had brought back with them a prodigious number of young slaves of both sexes, filling with them their camps and the markets of Asia. The successors of Salah-el-din, or Saladin, son of Aiüb, who usurped the title of sultan of Egypt in 1174, and who died in 1193, perceived that, having an opportunity, as Turkians, of corresponding with the coasts of the Caspian sea, they might form, at a cheap rate; a body of soldiers of tried courage and remarkable beauty. Accordingly one of them, *viz.* Malek Salah, about the year 1230, purchased to the number, as Volney says, of 12,000 of these young men, who were Tscherkasses (Circassians), Mingrelians, and Abazans. These he designed to be his guard and marine; and by training them up to military exercises, he soon obtained a body of the handsomest and best soldiers in Asia, though at the same time, as experience soon taught him, the most mutinous. This soldiery, like the Prætorian bands of Rome, ere long gave laws to their master. Malek Salah died in 1149, and was succeeded by his son Türan Shah, who in the following year captured St. Louis, and his army of 20,000 men. On the 11th of May 1250, the Mamlouks deposed and massacred Türan Shah, and assigned the sceptre to his step-mother, and afterwards to a Bey of the Aiübite race; and this event closed the dynasty of the Aiübites in Egypt. At this period commenced the dynasty of the Mamlouks. The first sovereigns of this denomination were the "Baharite Mamlouks," who were so styled, from having been originally employed as "mariners" on board the ships of the sultan of Egypt. These were Turks or Tartars from Kipzak. The first sovereign of this dynasty was Ezz-ed-din Moaz Ibegh, who began his reign A. D. 1254; and terminated it in the same year by assassination. Most of his successors closed their lives in the same manner. The last of the Baharite Mamlouks was Sheban Aseraf, who was the first sultan who ordered the sherifs, or descendants of the prophet, to wear a green turban. The next race of Mamlouks was denominated "Borgite Mamlouks;" it was of Circassian extract, and continued to rule Egypt till the French invasion. This dynasty commenced in 1382: but under succeeding sultans of this dynasty the Mamlouk aristocracy became gradually more and more precarious. From their first establishment, the effects corresponded with the means. Without any other bond of union than the interest of the moment,

or any public right to authority, but that of conquest, these Mamlouks, or military slaves, had no other rule of conduct and government than the violence of a licentious and insolent soldiery. The first leader whom they elected, having found employment for their turbulent spirit in the conquest of Syria, reigned 17 years; but the government of his successors was of shorter duration. The sword, the bow-string, or poison, public murder, or private assassination, have been the fate of a series of tyrants, 47 of whom are enumerated in the space of 257 years. At length, in 1517, Selim, sultan of the Ottomans, having taken and hanged Tomân Bey, their last chief, put a period to that dynasty. Selim was contented with abolishing the "monarchy" of the Mamlouks, but suffered their "aristocracy" to retain its former power, on certain conditions; the chief of which were, an annual tribute, obedience in matters of faith to the mufti of Constantinople, and the insertion of the name of the Ottoman emperors in the prayer, and on the coin. At the same time he projected such a form of government that the power, being distributed among the different members of the state, should preserve such an equilibrium as should keep them all dependent on himself. See **BEY**.

The Mamlouks, on obtaining the government of Egypt, adopted measures which seem to secure to them the possession of the country. The most efficacious is the precaution they have taken to degrade the military corps of the Arabs and Janizaries. These, and the other Turkish troops, are only a rabble of artizans and vagabonds, who guard the gates of those who pay them, and tremble in the presence of the Mamlouks, as much as the populace of Cairo. In reality, the whole military force of Egypt consists in the Mamlouks.

Some hundreds of these are dispersed throughout the country, and in the villages, to maintain the authority of their corps, collect the tributes, and improve every opportunity of extortion; but the main body continually remains at Cairo. From the computation of well-informed persons, it appears, their number cannot exceed 8500 men, reckoning Beys and Cachefs, common freed-men, and Mamlouks who are still slaves. In this number there is a multitude of youth under 20 and 22 years of age.

The most powerful house is that of Ibrahim Bey, who has about 600 Mamlouks. Next to him is Mourad, who has not above 400, but who, by his audacity and prodigality, forms a counterpoise to the insatiable avarice of his rival: the rest of the Beys, to the number of 13 or 20, have each of them from 50 to 200. Besides these, there is a great number of Mamlouks who may be called *individual*, who, being sprung from houses which are extinct, attach themselves sometimes to one, and sometimes to another, as they find it their interest, and are always ready to enter into the service of the best bidder. The Mamlouks, therefore, permit the inhabitants of Egypt to be carried only by mules or asses, reserving to themselves the exclusive privilege of riding on horseback; and of this they make sufficient use; for whether they are in town or the country, or if they only make a visit to the next door, they are never seen but on horseback. Their dress, as well as the support of their dignity, obliges them to this.

Their dress consists in a wide shirt of thin cotton, of a yellowish colour, over which they wear a sort of gown of Indian linen, or the light stuffs of Damascus and Aleppo. This robe, called *antari*, descends from the neck to the ankles, and folds over the fore-part of the body, towards the hips, where it is fastened by two strings. Over this first covering is a second, of the same form and width, the ample sleeves of which descend likewise to the finger

MAMALUKES.

ends. This is called a *coftan*, and is usually made of silk stuff, richer than the former. Both these are fastened at the waist by a long belt, which divides the whole dress into two bundles. Above them is a third, which is called *djouba*, which is of cloth without lining, and is made nearly in the same manner, only the sleeves are cut at the elbow. In winter, nay frequently even in summer, this *djouba* is lined with fur, and is converted into a pelisse. Lastly, over these three wrappers, they put on an outer garment, called the *benishe*. This is the cloak or robe of ceremony, and completely covers the whole body, even the ends of the fingers, which it would be deemed highly indecent to suffer to appear before the great. The whole habit, when the *benishe* is on, has the appearance of a long sack, from out of which is thrust a bare neck, and a bald head, covered with a turban. The turban of the Mamlouks, called a *kaouk*, is of a cylindrical shape, yellow, and turned up on the outside with a roll of muslin artificially folded. On their feet, they wear a sock of yellow leather, which reaches up to the heels, and slippers without quarters, always liable to be left on the road. But the most singular part of this dress is a sort of pantaloons, or trowsers, so long as to reach up to the chin, and so wide, that each of the legs is large enough to contain the whole body, and made of that kind of Venetian cloth which the French call *faulle*, which, although as pliant as the *d'Elbauf* cloth, is thicker than the *burre* of Rouen; and that they may walk more at their ease, they fasten, with a running fast, all the loose parts of the dress we have been describing.

As to their horse accoutrements, they are far from having adopted any modern improvements. Continually the slaves of custom, the horse's saddle among them is a clumsy frame, loaded with wood, leather, and iron, on which a trussquin rises behind, eight inches in height above the hips of the horseman. A pommel before projects four or five inches, so as to endanger his breast, should he stoop. Under the saddle, instead of a stuffed frame, they spread three thick woollen coverings, and the whole is fastened by a surcingle, which, instead of a buckle, is tied with leather thongs, in very complicated knots, and liable to slip. They use no crupper, but have a large martingale, which throws them on the shoulders of the horse. Each stirrup is a plate of copper longer and wider than the foot, with circular edges, an inch high in the middle and gradually declining toward each end; the edges are sharp, and are used instead of spurs, to make long wounds in the horse's sides. The common weight of a pair of these stirrups is between nine and ten pounds, and frequently exceeds twelve or thirteen. The saddle and saddle-cloths do not weigh less than five-and-twenty; thus the horse's furniture weighs above six-and-thirty pounds, which is so much the more ridiculous, as the Egyptian horses are very small.

The bridle is equally ill contrived; it is a kind of snaffle, but without a joint, and with a curb, which, being only an iron ring, binds the jaw so as to lacerate the skin, so that the bars are injured, and the horse absolutely has no mouth. This necessarily results from the practice of the Mamlouks, who, instead of managing the mouth, like us, destroy it by violent and sudden checks, which they employ particularly in a manœuvre peculiar to them. This consists in putting the horse on a full gallop, and suddenly stopping him, when at his highest speed. Checked thus by the bit, the horse bends in his hind legs, stiffens the fore, and slides along like a horse of wood. How much this manœuvre must injure the legs and mouth may easily be conceived; but the Mamlouks think it graceful, and it is adapted to their mode of fighting. Notwithstanding how-

ever their short stirrups, and the perpetual motion of their bodies, it cannot be denied that they are firm and vigorous horsemen, and that they have a warlike appearance, which pleases the eye even of a stranger; it must also be allowed, they have shewn more judgment in the choice of their arms.

The principal weapon, among the Mamlouks, is an English carbine, about thirty inches long, and of so large a bore as to discharge ten or twelve balls at a time, which, even without skill, cannot fail of great execution. They besides carry at their belt two large pistols, which are fastened to some part of their garments by a silk string. At the bow of the saddle sometimes hangs a heavy mace, to knock down their enemy, and on the left thigh is suspended, by a shoulder-belt, a crooked sabre, of a kind little known in Europe; the length of the blade, in a right line, from the hilt to the point, is not more than twenty-four inches, but measured in the curve is at least thirty. This form, which appears whimsical to us, has not been adopted without motives; experience teaches us, that the effect of a straight blade is limited to the place and moment of its fall, as it acts merely from pressure; a crooked blade, on the contrary, presenting its edge in retiring, slides by the effort of the arm, and continues its action longer. The Barbarians, who generally apply themselves most to the destructive arts, have not suffered this observation to escape them; and hence the use of scymetars, so general and so ancient in the Eastern world. The Mamlouks commonly procure theirs from Constantinople, and from Europe; but the Beys rival each other in Persian blades, and in sabres of the ancient steel of Damascus, for which they frequently pay as high as forty or fifty pounds sterling. The qualities they esteem in them are lightness, the equality and ring of the temper, the waving of the iron, and, above all, the keenness of the edge, which it must be allowed is exquisite; but these blades have the defect of being as brittle as glass.

The art of using the arms above described, constitutes the education of the Mamlouks, and the whole occupation of their lives. Every day, early in the morning, the greater part of them resort to a plain, without Cairo, and there, riding full speed, exercise themselves in drawing out their carbine expeditiously from the bandoleer, discharging it with good aim, and then throwing it under their thigh, to seize a pistol, which they fire and throw over their shoulder; immediately firing a second, and throwing it in the same manner, trusting to the string by which they are fastened, without losing time to return them to their place. The Beys who are present encourage them; and whoever breaks the earthen vessel which serves by way of butt, receives great commendations and money, as a recompence. They practise also the management of the sabre, and especially the *coup de revers* which cuts upwards, and is the most difficult to parry. Their blades are so keen, and they handle them so well, that many of them can cut a clew of wet cotton, like a piece of butter. They likewise shoot with bows and arrows, though they no longer use them in battle. But their favourite exercise is throwing the *djerid*: this word, which properly means a reed, is generally used to signify any staff thrown by the hand after the manner of the Roman pilum. Instead of staff, the Mamlouks make use of branches of the palm-tree, fresh stripped. These branches, which have the form of the stalk of an artichoke, are four feet long, and weigh five or six pounds. Armed with these, the cavaliers enter the lists, and riding full speed, throw them at each other from a considerable distance. The assailant, as soon

as he has thrown, turns his horse, and his antagonist pursues, and throws his in his turn. The horses, accustomed to this exercise, second their masters so well, that they seem also to share in the pleasure. But this pleasure is attended with danger; for some can dart this weapon with so much force, as frequently to wound, and sometimes mortally.

As to military skill the Mamlouks know nothing of our military arts; they have neither uniforms, nor order, nor discipline, nor even subordination. Their troops are a mob, their march a riot, their battles duels, and their war a scene of robbery and plunder, which ordinarily begins even in the very city of Cairo; and, at the moment when there is the least reason to expect it. A cabal gathers together, the Beys mount on horseback, the alarm spreads, and their adversaries appear: they charge each other in the street, sabre in hand: a few murders decide the quarrel, and the weakest or most timid is exiled. The people are mere cyphers in these affrays. Of what importance is it to them that their tyrants cut each other's throats? But it must not be imagined that they stand by indifferent spectators, that would be too dangerous in the midst of bullets and scymetars; every one makes his escape from the scene of action till tranquility is restored. Sometimes the populace pillage the houses of the exiled, which the conquerors never attempt to prevent.

In the field, they advance towards their enemies, mutual defiance pass, the attack begins, and every one chooses his man: they fire, if they can, and presently fall on with the sabre: it is then the manageableness of the horse and dexterity of the cavalier are displayed. If the former falls, the destruction of the latter is inevitable. In defeats, the valets, who are always present, remount their masters; and if there are no witnesses near, frequently knock them on the head to get the sequins they happen to have about them. The battle is often decided by the death of two or three of the combatants.

The interested and inconstant character of this militia, is a necessary consequence of its origin and constitution. The young peasant, sold in Mingrelia or Georgia, no sooner arrives in Egypt, than his ideas undergo a total alteration. A new and extraordinary scene opens before him, where every thing conduces to awaken his audacity and ambition; though now a slave, he seemed destined to become a master, and already assumes the spirit of his future condition. He calculates how far he is necessary to his patron, and obliges him to purchase his services and his zeal; these he measures by the salary he receives, or that which he expects; and as in such states money is the only motive, the chief attention of the master is to satisfy the avidity of his servants, in order to secure their attachment. Hence, that prodigality of the Beys, so ruinous to Egypt, which they pillage; that want of subordination in the Mamlouks, so fatal to the chiefs whom they despoil; and those intrigues, which never cease to agitate the whole nation. No sooner is a slave enfranchised than he aspires to the principal employments; and, who is to oppose his pretensions? In those who command, he discovers no superiority of talents which can impress him with respect; in them he only sees soldiers like himself, arrived at power by the decrees of fate; and if it please fate to favour him, he will attain it also, nor will he be less able in the art of governing, which consists only in taking money, and giving blows with the sabre.

From this system also has arisen an unbridled luxury, which, indulging the gratification of every imaginary want, has opened an unlimited field to the rapacity of the great. This luxury is so excessive, that there is not a Mamlouk, whose maintenance costs less than 2500 livres (or 104*l.*) and
VOL. XXII.

usually, and many of them cost double that sum. At every return of the Ramadan, they must have a new suit, French and Venetian cloths, and Damascus and India stuffs. They must often likewise be provided with new horses and harnesses. They must have pistols and sabres from Damascus, gilt stirrups, and saddles and bridles plated with silver. The chiefs, to distinguish them from the vulgar, must have trinkets, precious stones, Arabian horses of two or three hundred pounds value, shawls of Cashmere worth from five-and-twenty to fifty pounds each, and a variety of pelisses, the cheapest of which costs above twenty pounds. The women have rejected the ancient custom of wearing sequins on the head and breast, as not sufficiently splendid and costly, and in their stead have substituted diamonds, emeralds, rubies, and the finest pearls; and to their fondness for shawls and furs, have added a passion for Lyons stuffs and laces. When such luxuries are become the necessities of those whose authority is without controul, and who neither respect the rights of property, nor the life of their inferiors, it is easy to conceive what must be the condition of their subjects who are obliged to furnish them with whatever their caprice may require.

As to the manners of the Mamlouks, though born for the most part in the rites of the Greek church, and circumcised the moment they are bought, they are considered by the Turks themselves as renegadoes, void of faith and of religion. Strangers to each other, they are not bound by those natural ties which unite the rest of mankind. Without parents, without children, the past has done nothing for them, and they do nothing for the future. Ignorant and superstitious from education, they become ferocious from the murders they commit, perfidious from frequent cabals, seditious from tumults, and base, deceitful, and corrupted by every species of debauchery. They are, above all, addicted to that abominable wickedness which was at all times the vice of the Greeks and of the Tartars, and is the first lesson they receive from their masters. It is difficult to account for this taste, when we consider that they all have women, unless we suppose they seek in one sex, that poignancy of refusal which they do not permit the other. It is however very certain, that there is not a single Mamlouk but is polluted by this depravity; and the contagion has spread among the inhabitants of Cairo, and even the Christians of Syria who reside in that city. Brown's Travels; Sonnini's Travels; and Volney's Travels, vol. i.

MAMANDY, a town of Hindoostan, in the Carnatic; 35 miles E. of Coilpetta.

MAMANOOK, one of the Sooloo islands. N. lat. 6° 3' E. long. 121° 45'.

MAMARACPOUR, a town of Hindoostan, in Benares; 20 miles S.E. of Chunar.—Also, a town of Bengal; nine miles S. of Moorley.

MAMARONECK, a township of America, in West Chester county, New York, containing 512 inhabitants.

MAMAT, ST., a town of France, in the department of the Cantal, and chief place of a canton, in the district of Aurillac. The place contains 1408, and the canton 8181 inhabitants, on a territory of 325 kilometres, in 13 communes.—Also, a town of France, in the department of the Gard, and chief place of a canton, in the district of Nimes; nine miles N.W. of Nimes. The place contains 561, and the canton 6066 inhabitants, on a territory of 162½ kilometres, in 15 communes.

MAMBARY, a town of Hindoostan, in the province of Dindigul; 20 miles N. of Dindigul.

MAMBATENAWAN, a small island in the East
F f Indian

Indian sea; 50 miles N.E. of Borneo. N. lat. 6° 26'. E. long. 118° 45'.

MAMBIPILLY, a town of Hindoostan, in Mysore; 23 miles E.S.E. of Chinnabalarum.

MAMBURAO, a town on the W. coast of the island of Mindoro. N. lat. 13° 12'. E. long. 120° 45'.

MAMDEBAD, a town of Hindoostan, in Oude; 12 miles S.W. of Furruckabad.

MAMELLS, a small island on the N. side of lake Superior. N. lat. 48° 26'. W. long. 88° 4'.

MAMENDA, a town of Hindoostan, in the circar of Guntoor; 10 miles N.W. of Innaconda.

MAMERS, a town of France, and principal place of a district, in the department of the Sarthe; 23 miles N.N.E. of Le Mans. The place contains 5382, and the canton 15,913 inhabitants, on a territory of 212½ kilometres, in 22 communes.

MAMERTINI, in *Ancient Geography*, a people of Italy, in Campania; they passed over into Sicily, and established themselves at Messina, where they became so powerful, that they were masters of the place.

MAMERTIUM, a town of Italy, in Brutium, near the source of the Metaurus, and the Brutian forest. The name was formed of Mamers, which was the appellation of the god Mars, in the language of the country. It is probable, that the soldiers of whom Polybius speaks, who made themselves masters of Messina, and who were denominated Mamertins, derived their name from this town.

MAMERVAN, a town of Persian Armenia; 45 miles S.S.W. of Kars.

MAMHOFKA, a town of Poland, in the palatinate of Braclaw; 56 miles S.E. of Braclaw.

MAMIRA, in the *Materia Medica of the Arabians*, a root frequently mentioned by Avicenna, Serapion, and other of the Arabian writers. It seems mentioned as a poisonous drug, and is so described, that it seems to be the same with one species of the durunegi, or doricum of the same authors, and the common doricum of the shops, distinguished from the antithora, or other sort of durunegi, by the yellowness of the inside of the root. Avicenna says that it is hard and woody, and formed of knots or joints. This is the very description the same author gives of the durunegi of the first or poisonous kind. Paulus Ægineta says its root is composed of several joints also; and Alpagus calls it a nodose or jointed root. Some have supposed that the mamira was the same plant which we call smallcelandine, but this has no title to be placed among the plants suspected as poisonous, nor any other plea to be guessed at as the mamira, but only because its roots consist of many tubercles. Many things beside have been conjectured to be the mamira of the Greeks and Arabians, but the doricum seems to be the plant. See DORONICUM.

MAMISTA, in *Geography*, a town of Asia, in Cilicia, which was taken by the emperor Phocas, and which probably was the same with "Mamiltra," often mentioned by William of Tyre. See MOPSUESTIA.

MAMMA, in *Anat. my.* See BREAST.

MAMMA, *Cancer of.* See CANCER and SCHIRRES.

MAMMA, *Removal of.* The operation of amputating a diseased breast is described in the article EXTIRPATION.

MAMMALIA, in *Natural History*, the first class of animals in the Linnæan system, divided into seven orders, *viz.* primates, bruta, ferae, glires, pecora, bellua, and cete.

The characters of this class, according to the description of Linnæus, are as follow; the heart has two auricles and two ventricles; the blood is warm and red; the lungs respire regularly, alternate; the jaws are horizontally in-

cumbent on each other, and covered with lips, within which the teeth are, for the most part, included; they procreate by an intrans penis; and are viviparous and lactiferous: their organs of sense are the tongue, nostrils, eyes, ears, and cutaneous papillæ: they are covered with hair, which is thin on the animals of the warmer regions, and very scanty on aquatic animals: their motive organs are four legs and feet; except those which are entirely confined to the water, whose hinder legs are wanting: most have tails.

MAMMALIA, *Anatomy of,* has had much attention bestowed upon it, under the supposition of its being immediately applicable to the explanation of the functions of the human body. Particular parts of the subject have been successfully prosecuted with this view, both on the continent and in this country, but it is only lately that the anatomical history of the class has been formed into a system, chiefly by the labours of Cuvier and his assistants, who have not only filled up many details that were required, but have also added very interesting dissections of several quadrupeds, hitherto but little known.

Naturalists have almost universally included human beings in the class of mammalia, in consequence of their possessing the peculiar characters which distinguish this class from those of other animals. In this dictionary, however, the arrangement of animals for the purpose of describing their anatomy has been made under a contemplation of the mental endowments, and the social and moral propensities of man, which we conceive entitle him to a distinct rank in the scale of living beings; but if it were even otherwise, it became necessary, according to the plan of the dictionary, to separate man from mammalia, in order that human and comparative anatomy might be treated as distinct subjects.

Organs concerned in the Exercise of the vital Functions.

The Mouth and its contained Parts, or the Organs of Mastication.—The aperture and internal cavity of the mouth have a different form in mammalia from that in the human subject, with the exception of those species of monkey which approach mankind in general conformation.

The mouth of mammalia, in general, is capable of being opened widely, in consequence of the division of the lips being extended on each side backwards. This structure is most remarkable in the *beasts of prey*, and least so in the gnawing quadrupeds. The aperture of the mouth is peculiarly small in the *ant-eaters* and other *insectivorous* quadrupeds.

The cavity of the mouth, except in some of the *monkey* tribe, is considerably longer from before backwards, than in the transverse direction. This is particularly the case in the *ruminant* and *gnawing* quadrupeds, and is a shape of the mouth peculiarly well adapted for the minute division of the aliments, as they are more completely subjected to the action of the grinding teeth, and to the motions of the tongue, and the muscular parietes of the mouth.

The figure and magnitude of the cavity of the mouth depend upon the form and mechanism of the two jaws, but especially the lower one, which we shall describe when treating of the organs of motion.

The membrane which lines the mouth of mammalia is commonly more largely supplied with mucous glands than it is in the human subject; it is also more plainly covered by cuticle. Many of the *graminivorous* quadrupeds have a very thick cuticle spread over the inside of the mouth.

Several quadrupeds, and especially those which ruminate, have the roof and sides of the mouth covered with flat and pointed processes: these are mostly directed backwards, from which it would seem, that they are designed to facilitate

tate the passage of the food through the mouth. When these processes form soft pointed projections, somewhat like fringe on the inside of the lips, they may constitute a surface for receiving the impression of sapid bodies.

There are three sorts of *teeth* found in mammiferous animals. The first are employed in the simple division, and the grinding or chewing of the food: the second can only be used for seizing and detaining the prey until it is swallowed; and teeth of the third kind are intended for weapons or instruments of defence.

The first description of teeth admits of being subdivided into three sorts; first, the *incisive* or *cutting* teeth; secondly, the *canine* or *lacerating*; and thirdly, the *molar* or *grinding* teeth. We shall first describe the form and composition of the teeth, and afterwards speak of their mode of growth.

The *incisive* teeth are always situated, as a matter of necessity, in the front of the mouth.

They are commonly supposed to be formed of two substances; the proper osseous part which constitutes the basis of teeth in general, and the enamel. In some quadrupeds, however, we have found the third substance that enters into the composition of teeth, or the *crusta petrosa*, upon the fangs and sides of the incisors of some quadrupeds. The front teeth appear to be originally covered with *crusta petrosa* in the *horse*: certainly some of this substance remains in the cavity of the cutting edge, and upon the sides and fangs of the incisors of the *horse* during life.

The figure of the incisor teeth is more or less that of a wedge. In the *monkey* tribe, they almost resemble those of the human subject, having rather thin and flat bodies, sustained upon round stalks. In the *lemur*, the lower incisors have a singular position; they lie down before. In the *flying lemur* (*galeopithecus*) the front teeth are divided for some way from the edge into narrow processes, which stand parallel to each other, like the teeth of a comb. Some *cats* likewise have them denticulated upon the edge. Several *carnivorous* quadrupeds have the incisors terminating in one or more points.

The *saligrade* mammalia are distinguished by the peculiar structure of their incisive teeth. There are usually two of them in each jaw, placed in the centre of the front of the mouth. They have most commonly a thin sharp edge. In some species of the *rat* kind and the *squirrels*, the inferior incisors are pointed and compressed upon the sides. The enamel often does not surround the teeth, but is deposited only upon the anterior surface; the consequence of which is, that as the substance wears faster than the enamel, the latter always presents a sharp edge. The enamel is sometimes striated transversely, or is longitudinally grooved, as in the *bare*. There are several incisor teeth in the upper jaw of the *kanzurso*, but only two in the lower jaw: these are directed so much forwards, that they would seem to have but little concern in the division of the food. All the front teeth of the *kanzuroo* are covered with an enamel of so close a texture that it resembles porcelain, or a semi-vitrified substance. No animals employ their incisor teeth so constantly or with so much effect as the *saligrade* quadrupeds. Every person is well acquainted with the destructive powers of the *rat* kind. The *beaver* is able to gnaw trees across. It is upon the mode of using the front teeth that Cuvier has established his order in mammalia of *Rodentia*, which includes the same animals that we have denominated *saligrade*, from their leaping manner of progression. The incisive teeth of the *rodentia* are continually wearing away at the end, more especially those in the lower jaw; and to make up for the waste, they possess a long root, which contains a large vascular pulp that is always adding new osseous matter to the tooth. In

the *beaver*, and many of the *rat* genus, the length of the roots of the gnawing teeth is very remarkable. They extend backwards as far as the coronoid process of the lower jaw, and are contained in a canal which runs beneath the molar teeth in the substance of the maxillary bone. In the upper jaw this canal does not pass farther back than above the first molar tooth. In order to prove the continual wear and growth of the front teeth in the gnawing quadrupeds, it is only necessary to take one of this tribe that makes much use of its incisors, and sustain it for some time upon soft food, when it will be found that the lower teeth will grow so long as to turn up and penetrate the skull.

Amongst the large quadrupeds with several hoofs, or the *pachidermata* of Cuvier, there is considerable variety in the incisive teeth. They are wanting in the *elephant* and in the *African rhinoceros*. The *Asiatic rhinoceros* has in the upper jaw two large wedge-shaped teeth and two small lateral ones, which are cast early, and in the lower jaw there are two large cylindrical teeth, and two very small conic teeth between.

Cuvier remarks that, generally, the *many-hoofed* quadrupeds lose the whole or part of their incisors at a certain period of life, without their being replaced by others.

The *lisulca* want incisors in the upper jaw. The incisive teeth of the *horse* have a depression or slight cavity in their cutting surface. The enamel is continued into this cavity, and we have likewise discovered that the *crusta petrosa* passes into it, and gives a covering to the enamel, notwithstanding which the front teeth of the *horse* gradually wear down until these cavities are obliterated. The degree of waste which the incisors experience serves to determine the age of horses. The incisors of the *beaver*, *marmot*, *squirrel*, &c. are of a brown colour on their anterior surface. This would seem to be a stain of the enamel, and not an incrustation, such as takes place upon the teeth of several of the *clown-footed* quadrupeds. The latter is a dark coloured earthy substance, which receives a polish and a green metallic appearance upon the surface. This incrustation has always appeared to us to be of the nature of the bezoar stones, found in the alimentary canal of the same quadrupeds.

All the front teeth of the *seal* are conical and sharp-pointed, and are therefore more calculated for holding the animal's prey than dividing it.

The *morfe* (*trichecus rosmarus*) has two little truncated teeth, similar to molars, in the intermaxillary bone between the tusks, but no front teeth in the lower jaw.

The *canine* or *lacerating* teeth in the *ourang-outang*, and some other *monkeys*, have the same form of the incisors, in which circumstances these animals resemble the human subject. In most of the *monkey* kind, however, the teeth in the corners of the front of the mouth possess their proper characters, being pointed, conic, and so long as to pass each other in a greater or less degree when the jaws are shut. In some *baboons* the canine teeth are remarkably long.

The *lemurs* have them hooked and compressed upon the sides. They are long and conic in the *loris*. The *flying lemur* (*galeopithecus*) has them short, broad, and notched like a saw.

In some of the *plantigrade* mammalia, as the *hedge-hogs* and *skrews*, they do not rise much above the neighbouring teeth, and are bicuspid.

Blumenbach describes small canine teeth in the *bear* genus, which are situated immediately behind the principal canine. He found this remarkable structure to exist in the *brown bear* of the Alps, the *black bear*, the *polar bear*, and in the

MAMMALIA.

skeleton of one whose country is unknown, preserved in the National museum at Paris.

It is in the *digitigrade* quadrupeds that the form of the canine teeth is most perfect: in these they always are long, pointed, sharp, curved backwards, and generally those of one jaw pass the corresponding ones of the other jaw considerably, when the mouth is closed. The most striking instances of this are seen in the *tyger*, *pole-cat*, and *badger*.

Naturalists have considered the tusks of the *multungulata*, and of the *morfe*, *dugong*, and *narwhal* as canine teeth, which from their situation they are entitled to be considered, but as they can only be employed as weapons, we shall refer their description to a subsequent part of this article.

The canine teeth exist only amongst such of the *cloven-footed* quadrupeds as want the true horns. In the *stag*, *camel*, *dromedary*, and *lama*, they do not grow to any length, and appear to be in a great measure useless to these animals. The same structure obtains in the *horse*. The *tusks*, as they are popularly called, in this animal are short, and soon become blunt. They are peculiar to the male, who it is said in a wild state employs them as weapons, but this does not seem to be practicable.

The interior composition of the canine teeth agrees with that of the incisors. They are made in all the carnivorous quadrupeds of the common substance of the teeth, and covered with enamel; but we have discovered crusta petrosa upon the tusks of the *horse*, and we conceive it probable that it exists upon the canini of the other graminivorous beasts.

The *grinding* or *molar teeth* are always situated in the back part of the mouth, in order to gain the advantage of the lateral motion of the jaws, the supply of saliva, and the assistance of the tongue and cheeks in moving the food while it is undergoing trituration.

The figure and composition of the molares vary according to the nature of the food, and the habits of the animal to which they belong.

In the genus *Simia* the grinding teeth are very similar to those of the human subject: in some species of *monkey*, however, the last molar is larger than the rest, and furnished with a fifth tubercle; others have the last molar the smallest.

In the genus *Lemur* the molares begin to be pointed.

In the truly carnivorous quadrupeds they are (with the exception of the most posterior teeth) thin or conical, and end in either one or more sharp points. They are so placed in the two jaws likewise, that they are not exactly opposed to each other when the jaws are brought together, but pass each other in a degree, so as to divide rather than bruise and comminute the food.

The *cat* genus has only one molar tooth with a flat crown and blunt processes, which is situated in the upper jaw, and does not correspond with any teeth of the inferior jaw. It is often lost without any inconvenience.

The *weasels* and *martins* have a single tuberculated molar tooth at the back of both jaws. Those of the upper jaw are broad.

The *hyena* has one large molar, with blunt tubercles on each side the upper jaw, and a corresponding one with a pointed process in the lower jaw.

In the genus *Canis* there are two tuberculated molares on each side, above and below.

In the other *digitigrade* quadrupeds there is some little variety in the number and shape of the posterior tuberculated molares, which scarcely deserves notice.

In all these animals the molar teeth have the same composition as the canine and incisors, *i. e.* the form of the tooth depends upon the common osseous substance, which is covered

on that part seen above the gums by enamel: The molars of the carnivorous quadrupeds, from the manner in which they are used, do not wear.

The small *plantigrada*, such as the *hedge-hog*, the *mole*, and the *shrew*, and amongst the *pedimana*, the *opossum* tribe and the *perameles*, resemble each other with respect to the sharp tubercles upon several of their molar teeth. Cuvier has observed, that this form of the posterior molars belongs to the *insectivorous* quadrupeds, and that another general character of these animals is to have their superior teeth broader transversely than those below.

Amongst the *saltigrade* quadrupeds those that live upon a mixed food, as the *marmos* and the *rat* genus, have the molar teeth with tubercles, covered with enamel which does not wear. The other animals of this order have the crowns of the molares flat upon the top. The osseous substance of the teeth is not clothed but intermixed with layers of enamel, which produce a striated or grooved appearance on the surface as it wears. Some of the *saltigrada* have their molares entirely composed of transverse and vertical layers; others have the enamel only forming upon the crown some angles, circles, or other figures, without dividing the teeth into separate parts.

The *cavy* has in the upper jaw the first molar composed of one plate, the second of two, the third of three, the fourth of four, and the fifth of six. In the lower jaw each of the three first is made of two laminae and the last tooth of eleven laminae. Many of these laminae, especially anteriorly, are bifurcated. The grinding surface of these teeth is quite plain, and ascends obliquely from within outwards.

In the *guinea-pig* the molars are composed each of two bifurcated laminae. The molares of the *bare* and *rabbit* are likewise made of two laminae, but they are not bifurcated. The *phascolomys* has molares resembling those of the *cavy*.

In the *beaver* there is to each molar an angle returning to the external side from below, and to the internal from above, and three others more deep on the opposite side. When the teeth are worn by use, the last form only elongated and transverse ellipses upon the crown.

The *jerboa* of the Cape has but one angle returning to the internal side below, to the external above.

The molares in the *kangaroo* are furnished with tubercles, and those situated posteriorly have their tubercles united by transverse eminences.

The molar teeth of the *dormouse* have their crowns flat upon the grinding surface, which is regularly striated or grooved. The teeth appear, however, to receive only a superficial covering of fine pearl-coloured enamel.

In the *seal* the molars are, like all the other teeth, conical. The posterior ones, however, present some points. They cannot be used in any other manner than as incisive or lacerating teeth.

The *morfe* and *dugong* have the molares cylindrical in their shape, and with a flat grinding surface. The latter animal has them also grooved upon the side.

The *lamantin* has two rectilinear transverse eminences, except on the last molar teeth, which has three. They are notched before they are worn.

The teeth of the *cetacea*, as before observed, are not calculated to perform any of the masticating process; they can only be used to seize and detain the prey of these animals.

The most perfect examples of the true grinding teeth are found amongst the *large herbivorous* quadrupeds, particularly the *multungulata*. The teeth, necessarily, are continually wearing in those quadrupeds that are sustained, exclusively, upon vegetable matters. They are, therefore, most commonly

monly found to be intermixed with the enamel, and to be either covered externally or filled up with the *crusta petrosa*.

If a section be made of the grinding tooth of the *sheep*, the appearance of two crescents will be seen with an oblong dark coloured hole in the centre. The crescents are formed by the descending productions of enamel, covered on the inside by a layer of the *crusta petrosa*.

In the *cow*, and in the *clown-footed* beasts generally, the enamel and *crusta petrosa* are deposited in the interior of the teeth, so as to produce upon the grinding surface, or on a transverse section, the appearance of crescents, leaving a space in the centre, which is usually kept full of the masticated food of the animal. Mr. Home has supposed that the portions of food impacted in the cavities of the grinding teeth of graminivorous quadrupeds, supplies the place of *crusta petrosa*, and contributes to form the masticating surface. We have never observed it to be so hard as to answer this purpose, and the cavity which contains it is always, we believe, covered by a layer of the *crusta petrosa*.

In the graminivorous quadrupeds there is generally (and perhaps always, though not observed) more or less of the *crusta petrosa* deposited around the bodies of the molares as well as in the interior. When the teeth are a very little worn, the prominent parts appear uncovered, and shew the enamel, and the *crusta* seems only to have filled up the inequalities upon the surface. In the *sheep* there is no *crusta* apparent upon the outside of the tooth after it has been used; but it is not improbable, from analogy of structure, that when the grinders of the *sheep* first come out of the gums, that they have a thin covering of *crusta petrosa*.

The grinding surface of the molares of the *horse* presents an undulating or zig-zag line; formed by the osseous substance of the tooth and enamel encompassed in the *crusta petrosa*. The holes in the *horse's* teeth are much smaller than those of ruminating quadrupeds. Mr. Home has supposed that they originally gave passage to a blood-vessel, but in the *horse*, as well as the *bisulca*, the cavities of the teeth were occupied by the processes of the capsule which secreted the *crusta petrosa*.

In the *rhinoceros* and *daman* (*byrax*), the inferior molars are formed of two crescents placed in a row, and a little obliquely. The tooth farthest back in the mouth has three crescents, the anterior molar only one. The molares of the upper jaw are square, have a prominent line parallel to the external side, and two others which pass transversely and a little obliquely. The second of these transverse lines in the *rhinoceros* tends forwards a large hooked process. In the *daman* they have each a small one. The posterior molar of the upper jaw has somewhat of a triangular shape. The anterior tooth has but one transverse line.

In the *hippopotamus*, the molars in the middle part of both jaws have two pair of cones, set, as it were, back to back. These have two grooves on the opposite sides to those that are applied to each other: each cone, when worn down, presents on the top the figure of a trefoil. Both Dr. Blake and Mr. Home represent that the *crusta petrosa* does not enter into the composition of the teeth in the *hippopotamus* and the *rhinoceros*. It has, however, been since discovered, by Mr. Macartney, upon the whole of the external surface of the grinding teeth of the *hippopotamus*. It is a thin layer, which is seen worn away from the prominent parts, thus exposing the enamel, and occasioning the mistake respecting its existence. It is highly probable that a similar layer of the *crusta petrosa* is spread over the molar teeth of the *rhinoceros* when they are first formed.

The molares of the *elephant* are the plainest examples of the construction of graminivorous teeth. In the Asiatic

species, each grinder consists of a number of thin processes of the osseous substance, covered with enamel, united and enclosed by a mass of the *crusta petrosa*. These processes or plates are situated transversely with respect to the tooth; and when a vertical section is made of the latter, they have exactly the form of the teeth of a comb, imbedded in a third substance, which is the *crusta petrosa*. The grinding surface, after it has been used, presents a number of transverse narrow rough ridges, which are continuous at the edges of the tooth, so as to exhibit the appearance that would arise from the two sides of an oval being compressed together. They correspond to the osseous plates that are covered with the enamel. The interspaces between them are filled up with the *crusta petrosa*, which wears faster than either of the other two substances composing the teeth.

In the *African elephant* the processes of the osseous substance and the enamel are disposed in the *crusta petrosa* in such a manner, as to give the appearance of rough lines or ridges which form lozenges upon the grinding surface that touch each other in the middle of the tooth.

In the *fus ethiopicus* the molares are formed of several cylindrical processes of osseous substance and enamel consolidated together by the *crusta petrosa*: their grinding surface exhibits oval or angular figures in rows of three each.

The *mammoth*, or the animal whose fossil remains have been found on the banks of the Ohio, has long been known to possess molar teeth that have the same structure as those of carnivorous animals, notwithstanding that in the general its skeleton resembles the *elephant's* so much, that most people now believe it to have been the elephant of the American continent. The teeth of this animal are very large: the crown is entirely covered with a thick coat of enamel, and there is no *crusta petrosa* intermixed with it. The grinding surface is not flat, nor worn down, but presents two rows of short cones. The only appearance there is of friction presents itself upon the sides of these cones, or pyramidal eminences, and seems to be occasioned by the teeth of the two jaws fitting into each other, notwithstanding the molar teeth of the *mammoth* appear to be so well adapted for masticating animal food. If we may judge from the skeleton exhibited in this country, it is utterly impossible the *mammoth* could have been a beast of prey. It must have been disqualified from hunting by the structure of its limbs, the form of the head and neck, and the unwieldy figure of its whole body. It has been conjectured by some, and not improbably, that the *mammoth* subsisted upon the fish of the large rivers, on the banks of which its bones have been occasionally found.

The *duck-billed* animal of New Holland (*ornithorhynchus paradoxus*) has parts in the back of its mouth which correspond to the molars of other mammalia, but which have a different composition. They are not bone, but a horny substance: they are oblong, flat, and are merely fixed in the gums. There is one on each side in both jaws. Mr. Home has described, likewise, two horny processes in this animal on the back of the tongue, which he supposes to be designed to prevent the food being swallowed before it is sufficiently masticated.

The molar teeth of the *Cape ant-eater* (*Oryzoperus*, Geoff.) are extremely singular. They have the form of two cylinders joined to each other in the sides. They are entirely composed of a great number of minute, straight, and parallel tubes. If a transverse section be made of these teeth, it presents exactly the same appearance that is seen on cutting across a ratan, or other monocotyledon; that is, a number of very small pores. This tubular structure pervades the whole tooth, except at the grinding surface, which is solid.

Cuvier states, that there is no large cavity in the teeth of the *ornithorhynchus*.

The *Ornithorhynchus hystrix* has six transverse rows of pointed processes at the back of the palate, and about twenty similar ones on the base of the tongue: these have all a horny structure as the teeth of the *O. paradoxus*.

The *grampus* (*delphinus orca*) has been reported to have teeth in the palate. Cuvier supposes they may be horny processes, similar to those of the *O. hystrix* above-mentioned. But we have lately dissected this species of *delphinus*, and have found that nothing of the kind existed in the animal.

The organization and mode of growth of teeth, in general, have been much illustrated by observing their formation in the larger quadrupeds. The vascular tender substance which secretes the rudiment or nucleus of the tooth, and on which the tooth continues to grow, is popularly called the *nerve* in the human teeth, from the supposition of its being a prolongation of the dental branches of the maxillary nerves. In large teeth the pulp is easily seen to be formed of a peculiar spongy substance, which in the young animal is nearly as soft as jelly; its blood-vessels are extremely numerous and minute; its nerves are probably the same, for there is no large branch of the dental nerve contained in the pulp. The structure of the pulps of the teeth seems to resemble in a great degree that of the pulps of feathers and hairs, and of other excrementitious productions. See the articles FEATHERS, HAIRS, HORNS, &c.

In those animals which have the enamel passing down into the substance of the teeth, there are several processes of the pulp which produce a corresponding number of osseous shells or moulds, which have been called *denticuli* in speaking of the compound teeth of quadrupeds.

The osseous part of the teeth is more compact and hard, particularly in the molares of the large herbivorous quadrupeds, than it is in the teeth of the human subject. There is also a sensible difference between the composition of the external and internal parts of the osseous moulds of the teeth in quadrupeds. The first deposits of the pulp are very hard, streaked longitudinally of a yellow-greenish hue, and semi-transparent, like topaz. The parts deposited by the pulp afterwards are more opaque, of the common colour of bone, and shewing but little appearance of laminæ. They approach very nearly in structure the fangs, which being last formed, mostly resemble common bone. The gradual variation in the hardness of the osseous part of the teeth may be discerned, though less plainly, in the human subject. The streaked appearance above-mentioned, shews evidently that the osseous moulds of the teeth are secreted by the pulp in layers. The growth of this part of the tooth by layers has been likewise proved by Mr. Hunter's experiment of feeding a young pig with madder, when the teeth were forming. The osseous layers that were deposited during the use of the madder, were stained of the pink colour which this dye-stuff produces with phosphat of lime, and the portions of the tooth formed either before or after the madder had been employed, retained their natural colour. Cuvier describes the formation of the osseous moulds of the teeth as being effected by successive layers, as in the shells of the bivalve mollusca, which fact, he says, he had an opportunity of observing very satisfactorily in the gums of the teeth in the young elephant.

In *carnivorous* quadrupeds, as in *man*, the *roots* or *fangs* of the teeth are formed about the time that the crowns make their way through the gums, but in those *graminivorous* quadrupeds whose teeth are subjected to much wear, the roots are added some time after the eruption of the teeth

from the gums, by which means their proper length is preserved a longer time for mastication.

The structure of the enamel is very plainly seen in the teeth of the large quadrupeds. The eccentric arrangement of its fibres is particularly striking, when a section is made of any of the large grinding teeth, in which the enamel passes beyond the surface. The striæ are in these instances intermixed at their extremities with the *crusta petrosa*, and produce an appearance not unlike the barbs of a feather. Cuvier, in speaking of the enamel, compares it in the tooth of the young *elephant* to the fibres of asbestos, or to the pile of velvet. He observes, also, that these fibres are not always rectilinear, more frequently describing curves, of which the convexity is turned towards the crown of the tooth. The same arrangement of the fibres of the enamel, he says, exists in the *ruminant* quadrupeds. It has, however, escaped our attention.

It is well known that the enamel is a production of the capsules of the teeth, but it seems yet undecided whether it be a secretion immediately performed by the capsule, or a crystallization of the fluid contained in it. Mr. Home adopts the latter opinion, and supposes that the fluid in the capsules of the teeth is similar to synovia, which yields, upon chemical examination, a certain portion of phosphat of lime. It appears to us that the quantity of earthy matter found in synovia, supposing it to be the same in the fluid of the capsules of the teeth, is quite insufficient to account for the production of the enamel. There are only 21 parts of residue out of 970 parts of synovia, and but a small part of this residue is found to be phosphat of lime: besides, it should be observed, that the fibrous arrangement of the enamel is unlike what would probably be produced by a process of crystallization; the distribution of the enamel as to quantity also would be different from what it is upon the surface of the tooth: thus in some teeth there is little or no enamel upon the posterior surface, as in the incisors of the *gnawing* quadrupeds and the tusks of the *hippopotamus*.

Writers have disagreed with respect to the chemical composition of the enamel. Some have denied that it contains any animal matter; most, however, allow that it possesses a very little, upon which, most probably, its fibrous structure depends. Morrichini, a chemist at Rome, found fluoric acid in the enamel of the fossil teeth of the *elephant*, and afterwards in less quantity in the enamel of the human tooth, the different proportions he ascribed to the fossil teeth containing less animal matter. His experiments upon the human teeth go to shew that the enamel consists of 30 parts of animal substance, 22 parts of suat and phosphat of lime, with some magnetia, alumine, and carbonic acid. Mr. Hatchett and Mr. Brande both failed to detect any suat of lime in the enamel of teeth.

In the compound teeth of the *graminivorous* quadrupeds, where the enamel is extended from the surface between the *denticuli*, there are corresponding processes of the capsule which pass from the side of the gums. These have, in our opinion, been very improperly called ligaments by Mr. Home. They neither resemble ligaments in their functions or structure; they are much more like the pulps.

The third substance entering into the composition of the teeth is peculiar to certain mammiferous animals, and is not found in the human subject: the history of it, therefore, is only to be obtained from the late writers upon the teeth. It was first called *crusta petrosa* by Mr. Blake, a very appropriate name, as it appears like a stony or inorganic incrustation on the other substances of the teeth. Mr. Home, from considering that it more nearly approaches the nature of common bone than the other parts of the teeth, has termed

termed it the *osseous* or *bony portion*. The French writers have called it the *cement*, on account of its consolidating into one the different denticuli of the grinding teeth in *graminivorous* quadrupeds.

This substance has a pale yellow colour, is uniform in its texture, exhibiting neither fibres nor layers; it is more solid, dense, and heavy, but less hard, friable, or elastic, than the other parts of the tooth: it resembles more the callous or the osseous matter, poured out in consequence of inflammation, than any other substance in the animal body. It always is found deposited in the interstices or depressions of the teeth; and it is only after these are filled, that it appears to give a covering to the more prominent parts. The superficies of the *crusta petrosa* is never regular or smooth, until it is worn by mastication; and on many parts of the teeth, particularly about the roots, it presents the appearance of congealed drops of a matter which had been in a fused state. In the *cavy*, however, it contains a multitude of regularly arranged pores.

Tenon supposes that the *crusta petrosa* is produced by the ossification of the membrane which had enveloped the teeth. Mr. Blake ascribes its formation to the surface of the membrane opposite to that which secretes the enamel. Cuvier, however, gives a more rational account of the matter: he says, that the internal membrane of the capsule, after it has deposited the enamel, undergoes a change of structure, becoming thick, spongy, opaque, and more vascular, in order to furnish the *crusta petrosa*; that this last is shed, as it were, in drops, which form irregularly upon the surfaces of the teeth. When the internal membrane of the capsule is prolonged into processes that pass into the interstices of the compound teeth of the large quadrupeds, they become changed in like manner, after depositing the enamel in these situations, and then secrete the *crusta*, which serves to unite the denticuli into one tooth. This circumstance he had an advantageous opportunity of observing, during the development of the teeth in the *elephant*.

The *crusta petrosa* wears faster than either the osseous mould or enamel of the teeth, and thence its use in the herbivorous animals; the two first always presenting upon the grinding surface of the teeth certain eminences, which vary in their figure in different species, as already described, and which operate in the division of the food in the same manner as the irregular eminences on mill-stones.

The *succession* of the teeth is regulated in mammalia in general as in the human subject. The front teeth are replaced by larger ones, at an early age; and after these and the grinders all come forth, they remain during the life of the animal. In those quadrupeds which employ their teeth in a way that subjects them to much wear, particular provisions become necessary. We have already mentioned, that the gnawing teeth of the *saligrade* mammalia continue to grow in the same proportion as they wear; and the consumption of the grinding teeth, in some of the large herbivorous quadrupeds, is supplied by a succession not only of fresh teeth, but by the manner in which these come forth from the jaw.

The *elephant* affords the most striking example of this mode of succession. Although this animal has the rudiments of several teeth formed in its jaws, we never find more than two on each side of both jaws at once, *i. e.* eight grinders in the whole: often there is only one apparent in each side of both jaws. The molars of the *elephant*, as before observed, are compound, or consist of several laminæ or denticuli, united together by *crusta petrosa*. The first, or milk grinder, as it is called, pushes through the gum eight or ten days after birth, and is not completely exposed until the

third month: it consists of four laminæ or denticuli. The second grinders, which consist each of eight or nine denticuli, are uncovered in two years. In proportion as the new teeth appear, the preceding ones gradually wear down, and finally have their fangs, and the sockets which contain them, removed by absorption. The whole of a tooth is never seen in the mouth at any one time: indeed it does not exist; for the posterior portion of the tooth is not completely formed, and does not penetrate the gum, until the anterior portion is entirely worn down. Thus a grinder, consisting of twelve or fourteen denticuli, will have the anterior part worn, and even absorbed, a few denticuli of the middle partially worn and in use, and the posterior denticuli imbedded in the jaw, and their fangs in a state of growth, all at the same moment. This mode of growth and presentation of the teeth in the *elephant* is admirably calculated for maintaining the grinding surface.

In proportion to the *elephant's* age, the new grinders are formed, larger and of a greater number of denticuli, by which they remain longer in use. Thus the third set have each twelve or thirteen denticuli. They begin to appear when the second set have been all exposed, and displace these at six years of the animal's age. The fourth set of grinders are made of fifteen denticuli, and present the different parts of their grinding surface from the sixth to the ninth year of age. From the fourth set to the eighth the number of denticuli varies from fifteen to twenty-three, which is the greatest number that has yet been discovered in the grinding teeth of the *elephant*. The periods at which the last sets of teeth penetrate the gums have not been clearly ascertained; but it is supposed by Mr. Corfe, who has paid much attention to this subject, that each set requires one year longer for its development than the set preceding it.

Mr. Home has discovered that the teeth of the *su: athiopicus*, which are composed of several denticuli, have a mode of succession similar to what has been described in the *elephant*. He concludes from hence, that this animal has greater longevity than the others of the same genus.

Something of the same kind exists in the *wild boar*, and in the *animal incognitum*, according to Mr. Home's observations.

The periods at which the molars of the *horse* come forth, and are shed, have been lately ascertained by Mr. Tenon; by which it appears that the anterior molars are shed, and the posterior are late in appearing: the last molar cuts the gum only at the fifth or sixth year. The milk grinders of the *horse* are oblong at first from before backwards; but, by the pressure of those behind, become square: the teeth which replace them are also square.

The mode of succession is nearly the same in the teeth of the ruminating quadrupeds.

It is only upon animals which live in a domestic state, that accurate observations can be made with respect to the succession of the teeth. This partly accounts for the very few number of facts known upon the subject. Blake states, that the grinders of the *beaver* present themselves in a manner somewhat similar to what has been described in the *elephant*.

The second kind of teeth, or those for seizing and detaining the prey of the animal, are found in the *cetaceous* tribe of mammalia.

In the genus *delphinus*, the teeth are numerous in both jaws. They are nearly conical in their form; those of the *porpoise*, however, have the bodies of the teeth flattened, and the roots cylindrical. In the *grampus*, the natural shape is very much altered by wearing. In this genus, the teeth are lodged in regular bony alveoli; and we have ascertained that

a succession is kept up, by new teeth forming in the bottom of the sockets, which push out the old ones as they are worn down.

The teeth of the genus *delphinus* are composed only of two substances: the usual osseous part, which constitutes the mould or basis of all teeth; and a cortical substance of an intermediate texture between enamel and crusta petrosa. In the *porpoise* this external part is hard and polished, and does not readily wear; but in the *grampus* we have found it to be scarcely, if at all, different from the common crusta petrosa, and to wear like it faster than the osseous substance of the teeth. In fact, there is a gradation to be observed in the cortical part of the teeth of different animals, from the pure crystalline enamel to the opaque and comparatively soft incrustation found in the true graminivorous teeth. This variation might be expected, when we consider that both these substances are secretions of the internal membrane of the capsules of the teeth.

In the *spermaceti whales* (*physeter*), the teeth are situated in the lower jaw, and received into corresponding sockets of the upper jaw. They are conical, according to Hunter, at both extremities, and are not placed in alveoli, but grow in the gums. In a specimen we possess, the root of the tooth is nearly as large as any other part; the crown is worn into the shape of a compressed pyramid; and the cortical part resembles almost exactly crusta petrosa in its texture, and not enamel: it is extended entirely over the root of the tooth.

Hunter states that the small *bottle-nose whale* has a number of conical teeth in both jaws, viz. forty-six in the upper jaw, and fifty in the lower. He supposed that the teeth of the whale tribe were renewed by the jaws growing forwards, and being absorbed at the symphysis, while new teeth made their appearance in the posterior part of the jaws.

The *narwhal* (*monodon*) has only the two remarkable tusks, which we shall speak of under the head of the weapons of mammalia.

The *hyperodon*, formerly placed in the genus *delphinus*, but lately separated by Lacepede, is said to have teeth in the palate, similar to those of the *ornithorhynchus*, and also in the jaws.

But the most singular apparatus for retaining the prey in the mouth is the *whale-bone* of the *true whales*. This substance resembles, in its organization and mode of growth, *hair*, *horn*, and *feathers*, &c. (See these words in this dictionary.) The whale-bone is situated only in the palate and upper jaw: it forms a great number of lamellæ, even so many, according to Hunter, as 300 on each side of the mouth. These are of various sizes and lengths. Towards the interior of the mouth they are very short, about six inches; and become gradually wider and longer, as they approach the posterior and outer part of the palate and jaws: the most external lamellæ in the large *whale-bone whale* are stated by Hunter as measuring 12 or 15 feet long, and 15 inches broad. According to Cuvier, they measure 10 feet long. All the plates are placed transversely, with respect to the line of the body, and growing downwards, their unequal lengths give the palate and upper jaw the figure of a vault, or the interior of the roof of a house.

The plates of *whale-bone* are always found to terminate in a number of long fibres or hairs. This has hitherto been considered the effect of a mechanical division of the end of the plate from use; but these fibres are, at least when first formed, round and smooth, and of a thickness in some degree proportioned to the size of the lamina to which they belong, which makes it probable that the interior part of the plates consists of round fibres agglutinated into one

mass, somewhat in the manner of the horn of the *rhinoceros*. The superficies of the plates of whale-bone is smooth, and appears to have a lamellated form.

The lamellæ of whale-bone are hollow at their root, and are penetrated for some way by pulps, in the same manner as hairs. The interior parts of the whale-bone are secreted by the pulps, and the external layer by the same vascular substance extended upon the jaws. This likewise secretes a whitish horny substance, which surrounds and fills the interspaces of the basis of the plates.

Both the plates and the intermediate substance are worn by use, and renewed by a continual growth. The external part of the plates very soon, (or rather, we believe, immediately upon their protrusion,) breaks off in scales, and exposes the fibrous or hairy appearance at the extremity of the plates. As the hair wears, more of the external part of the plate gives way, so that the end of the plate that is turned towards the mouth always terminates in loose fibres.

The white intermediate substance, when it grows as high as the edge of the skin of the jaw, becomes soft, and decays away like old cuticle.

The *third description of teeth*, or those exclusively intended for *weapons*, usually occupy the situation of the canine or lacerating teeth. They are peculiar to the class of the large quadrupeds with several hoofs, or the *multungulata*, to two of the genus *trichecus*, and to the *narwhal*. Naturalists have so often described the form of these defences, that it is unnecessary to repeat the account of it here.

The interior substance of the *tusks* has been distinguished by the name of *ivory*: its composition is somewhat different from the bony part of teeth in general. In the *elephant* the ivory is less hard than in other animals; it likewise becomes sooner yellow on exposure to the air: it is marked by many curved lines, which run from the centre to the circumference of the tusk. The cortical part in the *elephant* is smooth and harder than the rest of the tusk. Cuvier believes it possesses a thin layer of enamel; but in our opinion, the superficies of the tusk is crusta petrosa.

In the *hippopotamus* the substance of the tusks is hard, and regularly striated. There is a moderately thick layer of fine crystalline enamel on the fore part of the tusks.

The ivory in the tusks of the *fus athiopicus*, Cuvier states to be nearly similar to the preceding. In the common *boar* there are no striæ to be observed, but sometimes layers of a brown substance.

The massy tusks of the *mongoose* are very dense in their structure, and want the striated appearance. The middle part of the tusk is formed of little round grains, not arranged in any order, but like the stone called *pudding-stone*. The ivory of the *dugong* has a uniform composition.

The singular teeth, or horns, as they are sometimes called, of the *narwhal*, have appeared to us to consist of an osseous substance throughout, which is similar to the crusta petrosa of the teeth in quadrupeds. The superficies is polished, as it would seem, by friction. The spirally grooved appearance of these teeth it is very difficult to explain, either with respect to its production or its use.

All the tusks of mammalia appear to continue to grow during the animal's life. The cavity in the root remains of a considerable size, and is always filled by a vascular pulp. The protracted growth of this sort of teeth has produced some effects that have been made use of as arguments for the existence of vascularity and organic actions in the earthy substances of the teeth. Thus, several instances have been discovered of balls, spear-heads, &c. being lodged in the tusks of *elephants*, and being surrounded by osseous matter, evidently deposited in consequence of inflammation. In all

marked with a groove along the superior surface. He states that the usual muscles of the tongue, particularly the *genio-glossus*, were very strong.

According to Cuvier in the *dolphin* (*delphinus delphis*) the *stylo-glossi* muscles arise from the superior and anterior edge of the styloid bone. The *hyo-glossus* comes from the middle of the convexity of the body of the os hyoides. There is but one *mylo-glossus*, the fibres of which proceed obliquely backward and inward, from the anterior circumference of the lower jaw towards the tongue.

There is a curious tendinous fasciculus under the tongue of the *dog*, which is popularly known by the name of the *worm*. It lies in a kind of membranous sheath, and has no connection, like other tendons, to any muscle.

Casserus thought it was useful to the dog in the peculiar method of taking liquids by *lapping*, and Blumenbach is inclined to agree with him in this opinion, from finding the same sort of tendon under the tongue of an *opossum* he had observed to drink, by lapping as dogs do.

A very dangerous notion has been entertained since the days of Pliny, that removing the worm from the tongue of a dog will prevent the animal becoming afterwards mad. Another opinion, which is probably as ill founded, is that dogs which have been wormed, if they should be affected with hydrophobia, will not shew any disposition to bite. The credulity which has always prevailed respecting the mode of preventing and of curing this disease, has been attended with the most mischievous effects in superseding the only rational means of security.

The tongue, as an instrument of manducation, is very actively employed. Its muscles give it the power of moving in every possible direction, and therefore of conveying the food from any one part of the mouth to another; it places the unbroken aliments between the grinding teeth; retains them there until they are sufficiently divided; and then carries them into the pharynx to be swallowed. The performance of these actions requires a nice feeling in the tongue, which it is known to possess in an eminent degree. Besides being an organ of taste, the tongue has a more discriminating touch than any other part of the body, and hence it is employed by jewellers and other artists in ascertaining properties that would escape the examination of the other senses.

The spiculae upon the surface of the tongue in many quadrupeds are calculated to improve the prehensile powers of this member in a great degree. In the *cat* genus these are horny processes, which are so sharp and strong, that they will tear off the skin in licking it. Many of the *herbivorous* quadrupeds, likewise, have the tongue armed with processes, which are serviceable in tearing up their food. The horny processes on the back of the tongue of the *ornithorhynchus* should perhaps be classed with the papillae of that organ, instead of being placed amongst the teeth.

Fig. 11. 1. Plate I. of the *Anatomy of Mammalia*, represents the peculiar muscles of the tongue in the *echidna*: *a* is the *mylo-hyoideus* muscle; *b* its assitant portion; *c*, a part of the *genio-hyoideus*; *d*, the *genio-glossus*, with its additional portion, *e*, are turned aside; *f* is the inferior layer of the *mylo-glossus*, separated from the palatine membrane, by which the superior layer of this muscle is seen at *g*; *h h h* indicate the *sterno-glossus*, terminating in successive fasciculi in the musculus annularis; *i i i* shew the annular muscle partially exposed, and at one place cut and turned back to expose the *sterno-glossus* passing through it; *k* is the membrane covering the tongue.

The *salivary* glands are the same in number, with a very

few exceptions, in mammalia as in the human subject. The *buccales* and *labiales*, however, are often hardly perceptible. The structure of the salivary glands is essentially the same in all cases; we have only to point out some varieties in the relative size of the glands, to notice those instances where one or all of them may be absent, and to describe some auxiliary glands which exist in a few species.

The salivary system is less striking in the *carnivorous* quadrupeds, than in those that consume vegetable food. The *parotids* are diminished in particular, being generally as small as the sub-maxillary glands, and sometimes even smaller; as may be observed in the *bat*, the *dog*, and the *American opossum* (*didelphis virginiana*). The texture of the salivary glands also is firmer, and their colour more red in the *carnivorous* than other quadrupeds.

The *sublingual* glands are not found in the *cat*, and in the *dog* they are but the prolongation of the *sub-maxillary*.

The *molar* glands, which are so small and obscure in man, are often very plain, and indeed considerable in quadrupeds. In the *cat* they form a close oval mass. In the *dog* they make an uninterrupted series, extended opposite the inferior molar teeth. In this animal there is a salivary gland, also situated in the zygomatic fossa; it is half the size of the sub-maxillary gland: it ascends as far as under the globe of the eye: its duct, which is very large, descends behind the superior jaw, and opens into the mouth, at the extremity of the alveolar border of the superior maxillary bone.

The *saligrade* mammalia have the salivary glands larger than the *carnivorous* or *digitigrade*, but, like them, the glands which pour out their fluid into the front of the mouth exceed the *parotids* in size.

The *tardigrade* mammalia have the parotids smaller than the sub-maxillary glands.

There are greater varieties to be observed in the salivary system of the *edentata* than in that of any other tribe of mammalia.

In the *two-toed ant-eater*, the *sub-maxillary* glands are of great size, they form a cone-shaped mass, which covers the fore-part of the neck, and the top of the breast. They are sunk in between the mammae, opposite the sternum, and extend forwards as far as the larynx. They then proceed upon the sides of the neck, and ascending round the ears furnish a narrow process, which passes forwards between the masseter and mylo-hyoideus muscles. Although this gland seems to be only one mass, it appeared to Cuvier, from whom this account is borrowed, to have two principal excretory ducts, which insinuate themselves along the edge of the mylo-hyoideus, and accompanying this muscle on each side as far as behind the arch of the chin, where they open into the mouth. Cuvier, however, speaks doubtfully of this description, as the subject from which it was taken had not been well preserved.

The *molar* glands in the same animal are united into one long mass, covered by the buccinator muscle.

The *sublingual* are formed of glandular grains disposed in a series under the membrane of the mouth, the length of the *genio-glossi* muscles.

The *parotids* appear to be replaced by the superior part of the glandular mass already described as the sub-maxillary glands.

Another salivary gland, which from its situation in some quadrupeds might be called the *zygomatic*, or *temporal*, also exists of a large size in the *two-toed ant-eater*. It is contiguous inferiorly to the upper edge of the masseter muscle: posteriorly and above, it corresponds to the temporal muscle, and it embraces anteriorly the globe of the eye. The sub-

MAMMALIA.

stance of this gland is more compact than that of the parotid: its duct opens behind the superior maxillary bone.

There is, lastly, a gland in the *ant-eaters*, the use of which is probably to furnish a mucus to the tongue, that is necessary for detaining the insects on which these quadrupeds subsist.

This gland is of an oval flattened figure, and descends before the tendon of the masseter, behind the angle of the lips, and then along the border of the lower lip, as far as the middle of it. The excretory duct of this gland opens externally in a groove at the commissure of the lips. When the gland is pressed, there issues from this orifice a white thick adhesive matter, which, no doubt, is destined for the use already mentioned.

In the *porcupine ant-eater*, (*echidna*), the *sub-maxillary* glands are extremely large. They extend far backwards. The lobes of which they are formed are very distinct, and the small excretory ducts of the glands are seen to terminate by plain orifices in a principal duct, the diameter of which is very considerable. The chief duct proceeds in the direction of the axis of the gland, upon the muscles which go to the tongue, and penetrates the membrane of the mouth very near the lymphic of the jaw.

There are also in the *echidna* two *sublingual* glands, of an oval form, smaller than the sub-maxillary, and with more compact lobes. They are situated behind the membrane of the mouth, on each side of the base of the tongue, and pour out their secretion through a number of small foramina at that place.

In the *mulungulata* the salivary system is extensive. The *pig* has two *sublingual* glands. The first is very narrow and long, composed of little lobes of a pale red colour, and accompanies the duct of the sub-maxillary gland from the angle of the jaw as far as the second sublingual gland, and opens by one small orifice. The other sublingual gland is placed anterior to this; it is square, flat, and composed of lobes of a larger size, and a redder colour, than those of the first sublingual gland. It has eight or ten excretory ducts, which perforate the membrane of the mouth in a row.

The *molar* glands of the *pig* are two long masses, which are of a reddish colour, and consist of large lobules, like the second sublingual of this animal.

In the *bisulca*, or *cloven-footed* quadrupeds, the salivary glands are of a great size, particularly those which are situated posteriorly with respect to the mouth.

In the *ox* and *sheep* there is a cluster of glands in the zygomatic fossa, which extends as high as the globe of the eye, and descends below the zygoma, under the masseter. Its excretory ducts open behind the last molar tooth.

The *zygomatic glands* in the *horse* are the continuation of the molars, which ascend behind the upper jaw to near the abductor of the eye. The *parotids* in the *horse* are very large, passing upwards behind the external ear, and downwards as far as the angle of the jaw.

In all those animals that inhabit the water, the salivary glands are either very small, or absent altogether. In the *common seal*, the *parotids*, the *sublingual*, and the *zygomatic* glands are wanting. There are two *sub-maxillary*, the one is larger than the other, and they have a common excretory duct, which opens as usual under the frænum of the tongue.

In the *cetacea* there is no vestige of salivary glands.

From the preceding description it will be seen the relative and absolute size of the salivary glands depend upon the use that is made of the teeth. When a species of food is taken that requires much mastication, the glands that pour their saliva into the sides of the mouth are particularly large.

When the food is of a kind that needs but little division, the salivary glands are smaller, especially those which furnish their fluid to the grinding teeth. In the *whale* tribe, which do not masticate at all, the salivary system is unnecessary, and accordingly does not exist. The great size of the salivary glands of the *insectivorous* quadrupeds would seem to be an exception to general rules, but it is to be remarked that in these animals the salivary glands immediately subservient to mastication are wanting. The great bulk of the others may, therefore, be necessary for entangling and detaining the ants upon the tongue, and facilitating their passage into the œsophagus.

No accurate or comparative examination has yet been made of the chemical properties of the saliva of quadrupeds, but the structure of the glands being similar, it is probable that the fluid they secrete does not differ materially from the saliva of the human subject.

In some mammalia, there are dilatations of the internal membrane and integuments of the mouth in which the food is deposited for a time previous to its being swallowed, and in which it is softened by maceration in the saliva. These cavities have received the names of *cheek pouches*, and *jaw sacs*.

A great number of species of *monkey* possess cheek pouches. They are not large, and the openings into the mouth are nearly as wide as the sacs themselves. Being situated opposite to the inferior molar teeth, they are well supplied with saliva from the parotids. When they are empty, the face of the monkey looks thin and sunken.

The *macerating pouches* connected with the mouth are much larger in the *hamster* (*mus cricetus*), and several other species of *mus* allied to the *hamster*. The most remarkable pouches, however, are found in the *Canada rat*, (*mus burjarius*), a species described by doctor Shaw in the 5th vol. of the Linnæan Transactions. He has distinguished it by a specific name expressive of its enormous pouches. In the figure he has given of it, the pouches are seen to hang down like two oval bags from the jaws, each of them equalling the size of the whole head.

Where the macerating pouches are large, they are said to be used for carrying the animal's food to their habitations, in which they deposit a winter store.

Pouches which appear strictly for macerating, have been described by Mr. Home in the *ornithorhynchus paradoxus*.

In *Plate II.* of the *Anatomy of Mammalia*, fig. 1. represents a front view of the head and shoulders of the *mus burjarius*, with its enormous pouches distended. The appearance of blood-vessels ramifying upon them is to be seen.

The *pharynx* of mammalia resembles in most particulars that of the human subject. Cuvier mentions some slight alterations in the direction and actions of the *stylo-pharyngeus* muscle. He states that in the *paca* this muscle seems to be the continuation of the *stylo-mastoideus*, and in the *elephant* it is united to the *stylo-hyoideus* as far as the top of the pharynx.

In addition to the usual muscles of the pharynx, many quadrupeds, particularly the *elephant*, *bear*, &c. have been observed to have the proper muscles of the tube of the œsophagus continued upon the bag of the pharynx. These layers Cuvier calls the *pharyngeus proprius*.

It is somewhat singular that the *uvula* is a part peculiar to *man* and the *monkey*.

The pharynx of the *whale* tribe is formed into two passages, by means of the curious larynx of these animals, which is elevated so high as to be inserted into the aperture, corresponding in some degree to the posterior nares. The structure of these parts will be better understood after the description of the larynx in the *whale*.

MAMMALIA.

Œsophagus.—This tube in most mammalia has the muscular coat formed of two layers, the fibres of which have a spiral direction; the external layer takes one course, the internal an opposite one; so that they always decussate each other. Some anatomists have supposed that these spiral muscles were peculiar to the œsophagus of ruminant quadrupeds, although they were figured in the *dog* above a century ago by Blaius. They have likewise been found by Cuvier in several quadrupeds, and by us in others, from which it would seem to be a tolerably general structure in mammalia. The muscular coat has been found to resemble that of the human subject in the *kangaroo*, in which animal it is also thicker than the muscular tunic of the rest of the alimentary canal.

The œsophagus of mammalia, generally speaking, is richly supplied with mucous glands.

The cuticular membrane is very plain in many quadrupeds, especially those that have the stomach partially lined with cuticle. There is a very strong white cuticle in the œsophagus of the *whale* tribe.

The internal membrane of the œsophagus exhibits longitudinal folds in many quadrupeds. Cuvier has remarked, besides these, some transverse folds about the middle of the œsophagus in several carnivorous mammalia, as the *tiger*, *lion*, *lynx*, and the *Virginian opossum*, in all of which these folds are very striking, forming a species of valves. They exist likewise, but in a slighter degree, in the *civet*, and in the *cougar* (*felis concolor*).

These valves, or transverse folds, are placed close to each other. They do not include the whole of the circumference of the œsophagus; but there are usually two or three which unite at an acute angle, in order to complete the circle.

The œsophagus of quadrupeds, in conveying substances into the stomach in a direction contrary to their gravity, exemplifies very clearly its functions in all animals. Its actions are always peristaltic, like those of the intestines. The successive contraction and dilatation of the different parts of the canal are obviously seen when a horse, or other long-necked quadruped, is drinking; the water does not pass in a stream along the gullet, but in the form of globes, the muscular fibres contracting behind them, as they pass onwards. The œsophagus is, therefore, always in a comparatively collapsed state, except at the very parts of the canal which contain the portions of food or drink.

The termination of the œsophagus is open and direct in the carnivorous quadrupeds, but in many of the herbivorous, particularly those with complicated stomachs, it is contracted, or enters obliquely. The œsophageal orifice of the stomach in the *horse* is diminished by a projection of the tunics, which has somewhat the appearance, and, as it is supposed, the effect of a valve. This structure is commonly believed to render the *horse* incapable of vomiting. We are, however, well informed that *horses* have been known to vomit when very active medicines have been employed. We believe, also, that it is equally difficult to excite vomiting in the ruminant animals, although they have the power of spontaneously bringing back the contents of the stomach into the mouth at all times. We must, therefore, seek for some other explanation for the indisposition to vomit in these animals, than the mode in which the œsophagus terminates in the stomach. Shall we attribute it to the parts of the stomach adjoining the œsophagus being less susceptible of stimuli, from being covered with cuticle? or is it that the medicines that have an emetic effect upon the human subject have a different operation upon them? It is a fact well known, that medicines have different, or even opposite effects upon different animals. The stomach of the *dog* is provoked to vomit by eating grass.

A peculiar glandular and moveable bag has been described behind the palate in the *camels*, which is supposed to carry water for moistening their fauces. Cuvier states it to exist only in the *dromedary*, in which it is thrust forth on the neck in the rutting season.

Stomach.—The history of this organ in mammalia forms one of the most interesting branches of comparative anatomy. The varieties in its form and structure, suited to the various kinds of food used by this class of animals, are highly instructive, and have been particularly investigated as being applicable to the explanation of the functions of the stomach in man.

The most simple form of the stomach belongs to those mammalia which subsist upon flesh. In many of the beasts of prey the stomach is nothing more than a slight dilatation of the alimentary canal. The cardiac or œsophageal end is larger than the pyloric, but there is no cul-de-sac, or dilated part placed out of the course of the substances through the viscus in which they can be detained. The best examples of the carnivorous stomach are found in the *pole cat*, and most of the genus *mustela*, the *dog*, *hyena*, *badger*, some of the genus *felis*, &c. In all these cases the smaller curvature, as it is called, is slightly hollowed, the dilatation being entirely in the great or lower curvature, and chiefly, as before observed, at the left or cardiac end. In the *seal* the stomach has great resemblance to that above described; the œsophagus forms even less of an angle with the stomach, but enters it at the end of the left extremity. The lesser curvature is not concave, but nearly presents a straight line, and there is near the pylorus a degree of circular contraction.

The enlargement of the great end of the stomach, and the inflection of the œsophagus somewhat nearer to the middle of the organ, is the first deviation of form to be observed. This figure is calculated to receive a larger quantity of food, and to retard in some degree its progress through the viscus; we accordingly meet with it in those animals that live upon a mixed food, or upon vegetable matters, either prepared by cooking, or some other means, to render them more digestible. This form of stomach exists in the *human subject*, in most of the *monkey* tribe, and of the *bats*, in some of the *plagiograde*, and many of the *saltiograde* mammalia.

The *orangs* resemble man with respect to the form of the stomach more than any other of the *monkey* genus. Several of the other species differ in the degree of cul-de-sac produced at the great end, by the situation of the œsophageal orifice, and some other immaterial circumstances which are pointed out in Cuvier's *Anatomie comparée*, tom. iii.

In the *galcopithecus* the pyloric half of the stomach is prolonged somewhat in the form of an intestine.

In the *brown bear* the portions on each side of the entrance of the œsophagus are directed towards the diaphragm. In the *hedge-hog*, also, the pyloric and cardiac ends of the stomach turn a little towards the diaphragm.

In the *brown coat* the stomach resembles in figure a pear, the pyloric end corresponding to the stalk, and the œsophagus being inserted into the side of the fruit.

The Parisian academicians described the stomach of the *lion* as being in the same direction as the œsophagus, until near the pylorus, when it turns upwards, or forms the small curvature, in the same manner as frequently is seen in the stomach of fishes. The academicians also found some dilated parts or pouches in the *lion's* stomach, but these differed in form and situation in different individuals. In the figure given by Cuvier of the *lion's* stomach, it has the same direction, but wants the dilated parts observed by the academicians. The preparations we have seen of the stomach of the *lion* resemble those of the *common cat*, in which

MAMMALIA.

which the cavity is larger than in the perfect carnivorous stomach.

The figure of the stomach is singular in the *garden squirrel* of Pennant (*myoxus nitela*). It is that of a globe, at the top of which both the œsophageal and pyloric orifices are situated close to each other. The tubes of the œsophagus and intestine are both small compared with the size of the stomach.

The form of the stomach is also globular in the *cape ant-eater* (*orycteropus*), but the part which leads to the intestine is a process from the right of the upper part of the globular sac: this prolongation has a very strong muscular coat.

In the *echidna* the stomach is large and has thin coats; the figure is oval; the cardiac and pyloric orifices are nearly at the two ends of the ellipsis: there is a slight oval enlargement at the origin of the intestines. The stomach is glandular near the pylorus, and the muscles are distinct at the same place. The internal membrane is thrown into some fine rugæ at the cardia, and forms larger and more numerous folds near the pylorus, which make a kind of radiated fringe. The pyloric orifice is not diminished by a circular fold, but the parietes of the stomach, which are thicker than those of the duodenum, form a projection into the latter.

The most extraordinary form found amongst the single stomachs of mammalia belongs to the *ornithorhynchus paradoxus*. It resembles a wine bottle, flat at the bottom, nearly straight on the sides, and tapering at the top. The œsophagus corresponds to the neck of the bottle. The duodenum arises from the part similar to the top of the body of the bottle, and soon becomes about half as wide as the stomach, which is extremely small in proportion to the rest of the alimentary canal, and to the size of the animal.

The *rhinoceros* has an unusual form of simple stomach. The cardiac portion is distinguished from the pyloric by a permanent contraction of the stomach. The former is an elongated oval. The œsophagus enters at nearly midway between the great end and the contracted part. The pyloric portion has a globular figure. The intestine arises out of the centre of it, and in a direction towards the great or left end of the stomach. The *rhinoceros* affords a real instance of a distinction of two portions of the stomach, without any process of the internal membrane forming a line of separation.

Mr. Home has fancied that a distinction of the stomach into two cavities exists in all single stomachs during life, by means of a permanent contraction of the muscular fibres of the middle of the stomach.

The effect of such an hour-glass contraction of the stomach would necessarily be to detain the food in the great end, either as a temporary or a preparatory reservoir, neither of which are required from the nature and preparation of the food of those animals which possess a simple stomach. Mr. Home's hypothesis tends to reduce the complicated and single stomachs to one kind, or class, and to break down all the distinctions established by nature, to correspond with the different kinds of food, and the various modes of its preparation.

It has frequently occurred to many experimental physiologists, and to ourselves, to see the figure of the stomach in the living body, but a regular and constant division into two portions by means of the muscular coat has not been remarked. We have observed different parts of the stomach in a contracted state: the muscles near the pyloric act most strongly, as might be expected, in order to propel the alimentary matters into the intestine, and the great

end of the stomach is in general found most distended, as being the part in which the food first arrives, and, consequently, is in some degree accumulated.

In many of the simple stomachs, the great end, or cardiac portion, is distinguished from the pyloric by having a thinner muscular coat: this difference of structure is usually accompanied by a larger capacity of that part. In some of these cases, likewise, the cuticle of the œsophagus is continued over the cardiac portion of the stomach. These facts prove the gradual approaches that are made in the structure of the stomach from a simple digestive organ, to the additional functions of a preparatory reservoir. The distinction of the stomach into two cavities, by means of structure and the prolongation of the great end into a more perfect cul-de-sac, are particularly well seen in several of the *rat* genus, and some other species of *saligrade* mammalia.

In some of the last mentioned tribe, the stomach is even more decidedly divided into two cavities than in the species to which we have alluded.

The *hamster* (*mus cricetus*), has the stomach formed of two cavities, the sides of which are conjoined, and communicate together by an orifice, apparently about the width of the duodenum, in the same animal. The œsophagus belongs to the left cavity, but enters at the junction of the two. The cardiac cavity or portion first extends outwards, and then turns up at the part corresponding to the great end of the stomach. The pyloric half is of a more irregular shape, and has thicker coats than the first. When distended, it has, in a degree, a facculated appearance from some dilated parts of its parietes. The communication between the two sides of the stomach is guarded by a fold, which is fringed upon the edge.

In the *water rat* the stomach is converted into two cavities, by means of a contraction situated a little to the right of the cardiac orifice, which is nearly about the middle of the stomach. The left or cardiac cavity is almost transparent from the thinness of its coats, shewing the division of the stomach to be designed to produce the effect of a reservoir.

The *short-tailed rat* of Pennant (*mus arvalis*) has the stomach divided in the same manner as the *water rat*.

The *lemming*, or *Lapland marmot* of Pennant, and the *mus lagurus* of Pallas, have also two cavities: they are separated in the latter animal by a very thick fold, that projects interiorly, and is fringed upon the edge.

The stomach of the *mole rat* of the Cape (*mus capensis*), is curved upon itself, and the œsophagus opens near to the pylorus; it is also divided into two cavities by a semi-lunar fold, which is furnished posteriorly by the internal coat.

In the *musk rat* (*mus zibethicus*), there is a contraction of the middle of the stomach, by which two cavities are formed.

The *mus aspalax*, and *mus œconomus*, have the stomach divided into three pouches. In the former there are two reflections of the internal membrane, which proceed from each side of the cardia. The one on the right is carried on throughout the whole circumference of the stomach. It has a denticulated edge, and there is a round gland in the most projecting part of its large curvature.

The stomach has a very singular conformation in the *kan-garoo*. It is greatly elongated, and doubled twice upon itself. It resembles very much the great intestine of the *barse*, not only in figure and great extent, for it nearly fills up the abdomen, but in being divided into a great number of sacculi by means of longitudinal muscular bands, such as exist upon the sides of the colon. The œsophagus

MAMMALIA.

gus enters the stomach at about $\frac{1}{4}$ th of its length from the end of the cul-de-sac. The cardiac end furnishes two processes; the external one has thick and glandular coats, while the other is smooth, whitish, and irregularly corrugated, like the rest of the internal surface in the cardiac portion of the stomach. This appearance of the internal membrane is preserved around the cardia, and in a part of the right portion where there are two long triangular bands. In the remainder of this portion, the inner surface is more grey, mucous, semi-transparent, uniform, and without rugæ. There are two appendices which arise beyond the middle of the pyloric portion, and are curved backwards, like two short cæca. The muscular coat forms a projection around the pylorus, by which it is much contracted, and the internal surface presents an annular burr at the same place, which consists of follicular glands. The muscular coat of the stomach in the *kangaroo* has transverse fibres going from the one longitudinal band to the other on the right portion, but on the left part of the organ there are only the longitudinal muscles to be seen.

The stomach of the *kangaroo rat* is divided into two portions, not only by its figure, but a difference of structure. The œsophagus opens at the place where the cardiac and pyloric cavities join, and there is a projecting fold which is continued from the œsophagus into the pyloric cavity, the design of which is evidently to conduct the food, under certain conditions, more immediately into the second cavity. The whole stomach possesses longitudinal bands, which produce contractions in its parietes, but this structure is particularly striking in the cardiac half, which is thrown into numerous deep sacs or pouches. The internal membrane of the left portion forms strong longitudinal rugæ on the posterior half of this cavity, and slight folds passing between some many-sided areas on the rest of the cardiac, and the beginning of the pyloric division of the stomach. The remainder of the latter is smooth, and without rugæ internally. There is a narrow gland, which extends the length of the first division of the stomach, and discharges its fluid through numerous small orifices upon the internal membrane.

In the *daman* (*byrax*), the stomach has two cavities. The first is nearly globular, and receives the œsophagus in its right side: the second is pyriform, and has the pylorus at the top, where there is a strong marked annular contraction. The part by which the two cavities are conjoined is very small.

The *porcupine* has the stomach consisting of three globular pouches. One corresponds to the cardiac portion; another to the pyloric: and the third, a smaller pouch than either, is placed between the two first, just at the termination of the œsophagus. Interiorly there is a fold which proceeds from the right of the cardia, and separates the left pouch from the two others. There is at the pylorus, on the side of the little pouch, a semi-lunar burr, composed of glands. The intestine and œsophagus are seen to arise close to each other, so that the whole figure gives the idea of a heart with the large vessels. The internal membrane is uniform throughout.

In the *vampire bat*, the œsophagus, before it enters the stomach, is dilated into a large oval sac, which communicates very freely with the cavity of the latter, and may therefore perhaps be considered as belonging to it. The stomach is long, resembling, in some degree, the colon of an animal. The left end is turned upwards, and at the extremity is curved backwards. Mr. Home describes this portion of the stomach as being divided into two dilatations, with a neck between them, the one having a rugous,

and the other a smooth surface. The distance from the œsophageal orifice to the pyloric is more than two-thirds of the whole length of the stomach: it first proceeds to the right side, and then turns back upon itself; the reflected part is puckered, or thrown into sacculi. The pylorus has a valve, which, when closed, will not permit air to pass through it.

The *speñre bat* has also the dilatation at the termination of the œsophagus; but all the other species of *vespertilio* appear to have a simple globular stomach.

We shall now proceed to the description of some stomachs which are more complicated in their forms than any hitherto mentioned.

In the *Pecari*, or *Mexican hog*, there are two remarkable processes from the cardiac portion of the stomach, which are turned downwards, and appear to render the cavity of three parts. There are several contractions dividing the pyloric portion of the stomach from the other. The cardiac portion is by much the larger. Daubenton has represented the stomach as being divided into a greater number of pouches or processes than are described by Cuvier or Home.

In the *hippopotamus* the cardiac portion contains three pouches, two of which only appear on the outside: the stomach then becomes long and cylindrical, like an intestine, and terminates in a narrow appendix, which opens into the duodenum. There are many transverse folds or valves in the first part of the cylindrical portion. The internal membrane is hard and granular in this part, from the last valve and in the two larger pouches: beyond the valves it is smooth and folded; there are no folds in the appendix, but the muscular coat of it is very thick, particularly around the pylorus.

The stomach is extremely complicated in the *tardigrade* quadrupeds, and approaches, in a considerable degree, the conformation of this organ in those that chew the cud. In the *two-toed sloth*, it appears, when viewed externally, to consist of two cavities. The left is very large in proportion to the œsophagus and the intestines; is nearly square in its figure, and exhibits, at least upon the anterior part, three elevations, or dilated parts. When the stomach is laid open, these are found to correspond to three cavities, or apartments, which are separated from each other, interiorly, by projections of the coats. The left, or cardiac division, of the organ in these animals should, therefore, be properly considered as three cavities. The pyloric, or right division of the stomach, is formed like an intestine, or rather, from its dilatation towards the middle, it resembles the simple carnivorous stomach in its figure. It is much smaller than the left portion, under which it is curved in the direction from right to left. The first half of it has very thin coats. The remainder has them thicker, particularly about the pylorus, the orifice of which is much contracted. These two parts of the right division of the stomach are stated to be separated by a semilunar fold. The first of these seems to be again divided by a little fold, finely denticulated upon the edge. The internal coat is different in the two portions. The first portion terminates in a little cul-de-sac, which is seen anteriorly upon the right side of the first, or cardiac division of the stomach, between two others. These little appendices appear to be glandular.

The inner coat is smooth in both the cardiac and pyloric divisions of the stomach of the *two-toed sloth*: it appears even to be tendinous in the two first cavities, or pouches, of the cardiac division.

In the *three-toed sloth*, the appendix of the second stomach

is much longer than in the preceding species, and is divided into three apartments by two longitudinal septa.

In both these species, the œsophagus, on entering the cardiac division of the stomach, becomes connected with a canal, which arrives, by a circuitous course, in the pyloric, or right division, into which it opens by a contracted orifice. The existence of such a communication as this would lead us to expect, that the *stots* had the power of ruminating; but Cuvier states, that he found both divisions of their stomach equally filled with some ligneous substances, reduced to a sort of mould, or earth. We shall refer the reader for a more particular account of the stomachs of the *tardigrade* mammalia to Cuvier's *Anatomic comparée*, tom. iii. Daubenton *Histoire Naturelle*, tom. xiii. and Wiedeman's *Archives*, vol. i.

We have next to describe the stomachs of the *ruminating* quadrupeds. There are some differences to be observed between the ruminants with horns, and those without. We shall first give an account of the stomachs of the horned ruminants, and as the most familiar example, take for this purpose the *ox*.

In this tribe of animals there are four stomachs, which fill up a great part of the abdominal cavity. The first stomach is called the *paunch*, (*rumen*, *penula*, *magnus venter*, &c.) It occupies the left side of the belly, and is larger in the adult than the three other stomachs taken together. It has an irregular globular figure. When laid open, it is found to be, in a certain degree, divided into three cavities, by means of two ridges, or projections of its coats, which cross it obliquely. The upper hollow contains the mouth of the second stomach, which is so large, that the two first stomachs should, perhaps, be considered as parts of the same cavity. The reflections of the coats, which form the ridges above mentioned, contain, besides the muscular coat, some tendons. The edges of the ridges are, therefore, thick and rounded. All the muscles of the paunch are particularly firm in their texture. The internal membrane is of a brown colour, and covered with strong papillæ in most places. The edges of the ridges are smooth. There is a thick cuticle lining the paunch, which may be detached by maceration, when it is seen to have given a covering to each of the papillæ. The contents of the paunch are the vegetable matters imperfectly masticated, and unmixed with any of the animal juices, or even the drink. It is in this stomach, therefore, that fermentation of green food is liable to occur. Many of the horned cattle have their body greatly distended by the extrication of air during this process in the paunch. The only remedy is to plunge a knife into the left loin of the beast, when the paunch will be penetrated, and an immense quantity of air will rush out. This expedient, although apparently so desperate, we believe, is never followed by any bad consequence. It is generally in the first stomach, rarely in the second, that the concretions of hair, or of vegetable fibres, or calcareous substances, are found. The *hair-balls*, occasionally met with in the paunch of the cow, are licked off from the body. They are curiously interwoven, and sometimes are covered with an earthy matter, which receives a fine polish. The balls found in the stomach of the *chamois* are composed chiefly of the fibres of the *ethusa meum*, and are covered with a fine black incrustation. The bezoar stones are earthy concretions, formed in a similar manner. See *BEZOAR*, in this Dictionary.

The second stomach of the *ox*, which is called the *honey-comb* bag, the *bonnet*, and *king's-hood*, (*reticulum*, *allula*, &c.) might be considered, if it were not for its internal structure, as a globular appendage of the paunch; it is placed upon the right side of the former, with which it communicates very

freely, as before-mentioned. The internal surface is elevated into thin folds, which unite to each other, so as to produce many-sided meshes, or superficial cells. The sides of the folds are grooved, and their edges denticulated. The area of the cells is papillated as the paunch, but with finer eminences. The second stomach is lined by a continuation of the cuticle which covers the first. The muscular coat is generally thicker and softer in the second than in the first stomach.

The œsophagus opens at the junction of the first and second stomachs, so as to be capable of communicating freely with the cavity of both, but the operations of swallowing and regurgitation are materially influenced by the actions of a muscular groove, or channel, which is continuous with the tube of the œsophagus, and ultimately leads into the third stomach. This groove is formed by two muscular columns, which proceed from the sides of the œsophageal orifice. The right band, or column, extends the length of the superior surface of the honey-comb stomach. The left runs within the edge of the opening from the first into the second stomach, and is prolonged upon the left surface of the latter. Each of these columns passes round the orifice leading from the second into the third stomach, decussating upon the inside of it. The internal membrane, where it covers these muscular columns, is thick and regularly plaited transversely. The membrane, on the contrary, is very thin between the columns, and forms, in the concave part of the groove, some longitudinal folds. There also is in this situation a layer of muscular fibres, which pass behind the groove, and connect one border of it with the other. This channel is the chief characteristic of the ruminating stomachs. When a portion of food is to be re-conveyed to the mouth, it is received into the groove, which, by the contraction of its muscles, approximates the two borders, and forms a perfect tube, and thus transmits the morsel into the œsophagus. Again, when rumination is finished, and the morsel swallowed, the groove forms a tube, and conveys it into the third stomach directly. When the food and water are first received into the stomach, the sides of the groove are necessarily open, but it is probable, at the same time, that the orifice of the third stomach is closed. The different actions of the groove are evidently subjected to the will of the animal, which is extremely curious, as it cannot be accounted for by any peculiarity in the anatomy of the part. The same system of nerves and vessels belong to the groove as to the stomach of other quadrupeds.

Mr. Home states, that the food contained in the paunch is always dry, and that the water the animal drinks passes into the second stomach, without mixing with the food in the first. The office of the honey-comb bag, therefore, seems to mix in a gradual and convenient manner the liquid and dry aliments. In this point of view, the first stomach is the receptacle of the meat; the second, of the drink, which will appear still more probable, after we have described the ruminating apparatus of the *camel*, &c.

The third stomach has received the names of *many plies*. (*echinus*, *cutipellis*, *omafum*, &c.) This cavity in the *ox* is larger than the honey-comb bag, and resembles in figure a hedge-hog rolled up, and thence one of its appellations. Its connection with the second stomach is very contracted. The cavity is filled with thin folds, or reflections of its coats, which arise from the smaller curvature, and have few edges at the large curvature corresponding to the back of the hedge-hog. These folds, or septa, are of unequal dimensions. According to Mr. Home's observations there are twenty-four septa, seven inches broad; about twenty-three that are four inches broad; and about forty-eight of one
inch

inch and a quarter in breadth. These are arranged in the following order. A broad one, with one of the narrowest next it; then a narrow one, with one of the narrowest next it; then a broad one; and so on. Whatever passes into the cavity of the third stomach must fall between these septa, and describe three-fourths of a circle, before it can arrive at the orifice of the fourth stomach, which is so near the other, that the direct line between them does not exceed three inches. The many plies are covered with cuticle as well as the first and second stomachs: they are covered also with little granular papillæ. The many plies form a projecting valve at the orifice of the fourth stomach, at which place the cuticle terminates.

The food that is found in the third, or plicated stomach, is distributed amongst the different septa in a compressed form. It has the consistence of thick paste, and a peculiarly unpleasent smell.

The fourth stomach is called the *red bag*, (*abomasum, fa-liscus, ventriculus intestinalis, &c.*) It has an elongated pyriform shape, somewhat like the simple digestive stomach of mammalia. According to Mr. Home, it measures in the *ox* about two feet nine inches in length: its internal membrane has eighteen longitudinal plicæ (nine on each side), beginning at its orifice, and extending about twenty-two inches in the cavity. They are four inches broad, and increase very much the internal surface. Beyond these, the inner coat forms some serpentine, or zig-zag rugæ. The cavity is a little enlarged near the pylorus, where there is a glandular body, which blocks up the pylorus when the parts are in a contracted state.

The stomachs of the other *ruminants with horns* differ very little from those of the *ox*. In the *deer*, the paunch has three projections, seen externally, which correspond to as many dilatations of its cavity. In the *deer, sheep, and antelope*, the papillæ, and other eminences of the inner coat of each of the stomachs, are less eminent than they are in the *ox*.

The stomachs of the *camel*, although agreeing in many respects with those above described, differ in some points materially. The best description of these stomachs has been given by Mr. Home, from which we shall chiefly borrow the present one.

The paunch of the *camel* is divided into two compartments, on its posterior side, by a prominent ridge, or column composed of muscle, which passes down from the right side of the orifice of the œsophagus. This column forms one side of the groove that proceeds from the cardia to the orifice of the second stomach, and it is continued beyond that to the lower part of the paunch. Beneath the orifice of the second stomach the column sends off, at right angles, from its left side, eight strong muscular bands, which afterwards form curved lines, till they are insensibly lost in the coats of the stomach. These are at equal distances from each other, and being intersected, in a regular way, by transverse muscular septa, form the muscular parietes of a number of large cells, situated on the left side of the back of the paunch. There is a series of twenty-one smaller cells of the same kind, which extend towards the right side of the paunch. They commence on the right of the chief muscular column, but have no connection with it. On the left side of the termination of the œsophagus, a broad muscular band has its origin from the coats of the first stomach, and passes down in the form of a fold parallel to the great ridge already described, and with it forms the groove as far as the entrance of the second stomach. After entering this cavity, it takes a new direction, passing along the upper

edge of it, and terminates within the orifice of the third stomach.

The orifice of the second stomach is at right angles with the side of the paunch: it is nearly closed when the muscular band, which passes through it, is not in action. It is a pendulous bag, in which there are twelve rows of cells, formed by as many strong muscular bands, passing in a transverse direction, and intersected by weaker muscular bands, so as to form the orifices of the cells. Above these cells, and between them and the muscle which passes along the upper part of the stomach, is a smooth surface extending from the orifice of this stomach to the termination in the third.

The second stomach of the *camel* neither receives the solid food in the first instance, as in the *ox*, nor does it afterwards pass into its cavity or cellular structure. The food goes first into the general cavity of the first stomach, and that portion of it which lies in the recess immediately below the entrance of the œsophagus, under which the cells are situated, is kept moist, and is readily returned into the mouth, along the groove formed for that purpose, by the action of the strong muscle, which surrounds this part of the stomach, so that the cellular portion of the first stomach in the *camel* performs the same office as the second in the *ruminants with horns*. While the *camel* is drinking, the action of the muscular band opens the orifice of the second stomach, at the same time that it directs the water into it; and when the cells of that cavity are full, the rest runs off into the cellular structure of the first stomach immediately below, and afterwards into the general cavity. It would appear that *camels*, when accustomed to go journeys in which they are kept for an unusual number of days without water, acquire the power of dilating the cells, so as to make them contain a more than ordinary quantity as a supply for their journey; at least such is the account given by those who have been in Egypt.

When the cud has been chewed, it has to pass along the upper part of the second stomach before it can reach the third. How this is effected, without its falling into the cellular portion, could not from any inspection of dried specimens be ascertained; but when the recent stomach is examined, the mode in which this is managed becomes obvious. At the time that the cud is to pass from the mouth, the muscular band contracts with so much force, that it not only opens the orifice of the second stomach, but, acting on the mouth of the third, brings it forwards into the second, by which means the muscular ridges that separate the rows of cells are brought close together, so as to exclude these cavities from the canal through which the cud passes.

It is this very curious mechanism which forms the peculiar character of the stomach of the *camel, dromedary, and lama*, fitting them to live in the sandy deserts, where the supplies of water are so precarious.

The third stomach of the *camel* is very small, and quite unlike that of the *ox*. It is nearly spherical; four inches in diameter; is not lined with cuticle; nor has it any septa projecting into it. It has a honey-comb appearance upon its internal surface, but this is so slight as to require a close inspection to perceive it. This stomach answers the purpose of retarding the progress of the food, and making it pass by small portions into the fourth cavity; effects which are produced by the leaves of the many plies of the *ox*, in a more perfect manner.

The fourth stomach of the *camel* has, for a great part of its length, the appearance of an intestine; it then contracts partially, and the lower portion has a near resemblance in its shape to the human stomach.

The whole length is four feet four inches: when laid open,

MAMMALIA.

the internal membrane of the upper portion is seen to be thrown into longitudinal narrow folds, which are continued for about three feet of its length: these terminate in a wadded appearance: the rugæ are large, as in the *ox*, but not so prominent, nor so serpentine in their course; and for the last nine inches the membrane has a villous appearance, as in the human stomach. Close to the pylorus there is a glandular mass of a conical shape, the larger end of which rests upon the orifice of the pylorus. The same gland exists in the *ox*, but it is not so conspicuous as in the *camel*. The aperture of the pylorus is also diminished, by the usual annular projection of the coats. Immediately succeeding the pylorus, there is a very considerable globular dilatation, appearing like a fifth cavity of the stomach. The duodenum arises abruptly from one side of it.

The description given of the stomachs of the *dromedary* by the Parisian dissectors, is so very brief and imperfect, that scarcely any knowledge can be obtained from it. They describe the four stomachs as succeeding each other in nearly the same line. The third as being very long, and the second as containing about 20 cells for holding water.

Cuvier has given a very excellent description of the ruminating stomachs of the *lama*, as he found them in an individual that had been born dead. The age is very necessary to bear in mind, as the size and even internal structure of the different cavities of the ruminating organs are much influenced by it. Thus, before the *calf* or *lamb* begins to feed upon grass, rumination cannot be performed; the milk passes immediately into the digestive stomach, the groove always forming itself into a tube during the act of deglutition; the paunch is small, and the fourth stomach large in relation to what it afterwards becomes, and the cells and other eminences of the two first stomachs are comparatively slight.

In the *young lama* dissected by Cuvier, the *paunch* had an irregular globular figure, being elevated upon some parts, to correspond with pouches or dilatations interiorly. It was larger than all the other three stomachs together; two of the pouches contained square water-cells, similar to those of the *camel*; one pouch had six rows of cells, each containing about 12, which could be discovered externally, by some swellings of the coats. The other pouch had only five similar cells. Between this pouch and the cardia, there was a third dilatation, which was the smallest of all, and exhibited some folds upon its inner surface, but no cells. The remainder of the inner coat of the paunch had some irregular folds, which, however, generally lay in the direction from before backwards.

The second stomach, placed anteriorly, and on the right of the paunch, was an oval bag, divided transversely by eight principal rows of cells, which were divided into smaller cells, and each of these terminated in a gutter grooved in a transverse direction, which was prolonged and lost in the paunch.

The channel leading from the œsophagus to the third stomach, was distinguished by a large fold, such as exists in the *camel*.

The third stomach was elongated and cylindrical; its internal surface exhibited some longitudinal folds, united to each other by transverse ones. These disappear towards the end.

The fourth stomach was not separated by any contraction. It was wider and shorter than the third, and turned backwards upon it. Its inner surface appeared villous, and presented on the posterior part some convolutions and irregular folds near the pylorus. A rounded glandular body projected into the cavity at the orifice of the pylorus, which it

completely closed as a valve. Immediately beyond the pylorus the canal was dilated into a round sac, as in the *camel*.

From the preceding descriptions of the stomachs in the *camel* and *lama*, it will be seen that the chief distinctions in the ruminants without horns, are the second stomach being exclusively designed for a reservoir of water; the third being a sort of assiduous digestive one: and from Cuvier's dissection of the *lama*, we may suppose the paunch of that animal is nearly as large before, as after rumination commences. These animals have long been known to carry a quantity of water in their stomach, which was only mixed with the food as occasion might require. This water is retained in the cells already described, by means of the muscular fibres surrounding their orifices, contracting so as to close the cells. The *camel*, it is said, will not drink every day, but when it does, it takes in between seven and eight gallons of water. All that found in the cells of the second stomach is perfectly pure and limpid, and hence it is, that the animal is sometimes killed when travelling in the deserts, for the sake of the water in its stomach.

The stomachs of the *southern lamantin*, and of the *cetacea*, are as complicated as those of the ruminant animals, although they do not perform the same office.

In the *southern lamantin* (*trichecus australis*), there are properly two stomachs with appendages from them. The first is globular in its figure, but longer in the transverse direction than any other. It receives the œsophagus into the middle of its anterior part. The internal membrane of this stomach is villous, and it has its cavity divided into two at the anterior part, by a fold which is on the right of the cardia. There is a little process or appendix from the side of the first stomach, the orifice leading into which is so small, that no food can pass into it. This process discharges a liquor into the stomach, and should therefore be considered as a gland. The second stomach is smaller than the first, and of a long shape; it gives origin at its commencement to two little processes; the one superior, the other inferior. The internal membrane is villous, and slightly corrugated transversely.

Anatomists are not agreed as to the number of stomachs in *cetacea*. Cuvier and Blumenbach reckon four. Hunter, on the contrary, described five in the *porpoise*, *grampus*, *dolphin*, and *piked whale*, and seven in the *bottle-nosed whale*. This difference arises from the manner in which the parts are considered, and not upon any errors of observation; perhaps it would be still more proper to view the two first cavities as the first and second stomachs, and the subsequent ones as belonging to the intestinal canal.

The first cavity in the *porpoise* is a large oval bag, into the top of which the œsophagus opens. It is lined with a thick cuticle. The other opening of this bag is near the œsophageal orifice, or, as one might state it, in the shoulder of the bag, the œsophagus constituting the neck. It seems not improbable, from the vicinity of these two apertures, that food may, under some circumstances, pass from the œsophagus directly into the second stomach. The communication of the first and second stomachs is extended into a short canal, into which the cuticle of the first passes and abruptly terminates. This canal is corrugated in the longitudinal direction.

The second stomach in the *porpoise* is considerably less than the first, and situated on the right side of it. It is likewise an oval cavity, but dilated or rounded at the ends. It is divided upon the anterior part by a deep contraction, which leaves on the right the appearance of a distinct cavity. This portion is that which some anatomists have

H h considered

considered as the third stomach. The internal surface is in both these cavities smooth and spongy, without cuticle, and forms rugæ, which cross each other at right angles.

The opening into the fourth cavity, or stomach, as it has been considered, is at the right side of the bottom of the cavity last described, and is marked by a decided annular contraction, similar to a pylorus. The fourth cavity also resembles exactly an intestine. It makes three serpentine turns, and terminates in the lower side of an oval sac, of an inconsiderable size, which is the *fourth stomach* of some authors, or the *fifth* of others. The coats of this cavity are thin, smooth internally, and tinged with bile, as it is into it, that the biliary and pancreatic ducts open, which is a strong reason, in addition to the form of these parts, for considering all, except the two first stomachs, as belonging to the intestine. At the place where the contraction and projection of the coats inwards form the second stomach into two cavities in the *grampus*, we have found two glandular masses. They are like roundish cakes in the coats; the one measures about seven inches and a half in diameter, the other about four inches. There are some ragged irregular depressions upon the inner surface, corresponding to these glands, which appear to be the outlets of mucous follicles upon a very large scale. The glandular cakes, therefore, probably take the place of the pyloric glands in other animals.

The projections of the inner coat in the stomachs of the *whales*, are much more remarkable than in the *porpoise* or *grampus*; the rugæ are very eminent, and in some there is a strong reticulation on the inner membrane that projects into folds, which are indented into each other.

In describing the stomachs of some mammalia, we have mentioned the existence of *cuticle* and *glands*, when these happened to have occurred along with other peculiarities. These points of structure are, however, so remarkable in other instances, that they deserve a distinct consideration.

The *cuticle* of the œsophagus is extended for some way into the stomachs of several of the *saligrade* animals, generally covering a little more than the great end, and terminating by a prominent denticulated edge, as instances of which we may mention some of the *rat* kind. There is some cuticle also in the stomach of the *kanzuroo*, the *common hog*, and the *pecari*. The cuticular covering of the great end exists in all the *solipeda*, whose stomachs are otherwise very simple in form and structure. It is obvious, that the portion of the cavity which is covered by cuticle, is incapable of performing any other function than that of a reservoir.

The *glands* that we have had occasion to notice in the preceding account of the digestive organs, were generally situated at the pylorus, and were not very remarkable as to size; but some mammalia have a glandular apparatus at the cardiac orifice of the stomach, which is very curious.

In the *beaver* there is a large oval mass of glands on the right side of the œsophageal orifice of the stomach. It consists interiorly of a number of cells, decreasing in size, and uniting with each other from the surface next the inside of the stomach. It pours out its liquor into the stomach through a number of irregularly-shaped holes. Mr. Home reckons 32 of these holes, which he states to be arranged upon three ridges, on the surface of the gland next the inside of the stomach; nine on each side of a middle ridge, and seven on each of the lateral ridges.

The glandular structure of the *beaver's* stomach has been long known, and was considered the only instance of the kind; but a similar apparatus was discovered several years ago in the stomach of the *common dormouse* by Mr. Ma-

cartney. The œsophagus, just before its entrance into the stomach, makes a serpentine turn, and at that place becomes greatly enlarged, and surrounded by a cellular glandular structure. The cells produce on the superficies of the gland a number of slight elevations, which give it the appearance of a mulberry. The entire size of the gland is, however, about that of a pea. The œsophagus, before it enters the gland, would scarcely receive a pin; and after the dilatation in the gland, it again contracts in a degree, where it opens into the stomach. The openings of the gland into the œsophagus are much fewer and larger in proportion than they are in the *beaver*, so that nearly the whole of the cellular structure can be seen by looking at the interior surface, if the part be distended or spread out. This gland approaches more nearly to the *bulbus glandulosus* of birds, than any similar structure does in the class mammalia. In Mr. Home's account of this gland, he appears to claim the discovery of the internal structure, although preparations and drawings of both the external and internal appearances were annually shewn by Mr. Macartney at his lectures, for seven years before Mr. Home wrote upon the subject.

In the *wombat*, there is a glandular mass that occupies a great part of the small curvature of the stomach, which almost exactly resembles the glands in the *beaver*. There are many irregular-shaped openings on the inner surface, within which are smaller openings or cells. A very fine plate of this structure has been published by Mr. Home in the *Phil. Trans.* for 1808.

A perfectly similar apparatus was found by Cuvier in the posterior part of the stomach of the *pangolin* (*manis pentadactyla*). The stomach of this animal is also remarkable on account of the great thickness of the coats towards the pylorus, which appears to operate in the same manner as the gizzards of birds, for the *pangolin* swallows small stones and gravel.

The *ornithorhynchus hystrix* is likewise reported to take sand into its stomach. These extraneous substances, in both cases, are, no doubt, designed to triturate the food, and supply the want of teeth in these animals.

Cuvier describes in the *northern lamantin* (*trichecus borealis*), an oval gland, as large as the human head. It is placed near the cardia, and appears to possess exactly the same structure with those above-mentioned. The fluid secreted is a whitish colour. Cuvier supposes, and with every appearance of probability, that the small appendix of the first stomach in the *southern lamantin* corresponds to this gland. The appendix is evidently designed for secreting a fluid, and not retaining the food: from the alliance between the two animals, therefore, it can scarcely be doubted, that the appendix and gland perform similar offices.

The use of the cardiac glands is commonly supposed to be for furnishing an extraordinary quantity of the gastric fluid, and Mr. Home endeavours to prove that similar glands, upon a smaller scale, exist in all stomachs. There are, however, some reasons for questioning this opinion. The structure of these cardiac glands, and of those small glandular pores that are generally found in the stomachs of mammalia, more nearly resembles that of mucous follicles than any other secretory apparatus. The fluid furnished by the glands of the stomach is in every respect similar to the mucus of the intestines. The situation of the cardiac glands, also, is not the most favourable for the application of a digestive fluid, it being immediately adjoining that portion of the stomach which receives the food in the first instance, and in which it is deposited for some time, as a reservoir in certain species. The cardiac glands might be supposed, perhaps with greater propriety,

propriety, to be designed for the secretion of a fluid capable of macerating and preparing the food for digestion, instead of a really solvent or assimilating liquor.

Plates II., III., and IV. of the *Anatomy of Mammalia*, are intended to exhibit the structure of the stomach. Fig. 2. Plate II. represents the stomach in the *ferret*, as an example of the form of this organ in the *carnivorous mammalia*. Fig. 3, of the same plate, is the stomach of the *garden squirrel* of Pennant (*myoxus nitela*): *a* is the œsophagus; *b*, the intestine arising close to it; *c*, the globular stomach. Fig. 4. exhibits the stomach of the *ornithorhynchus paradoxus*, which is selected on account of the singularity of its form: *a*, the œsophagus; *b*, the intestine; *c*, the bottle-shaped stomach; *d*, the biliary duct. Fig. 5. represents the double stomach of the *hamster*: *a*, the œsophagus; *b*, the cardiac half or portion of the stomach, much turned up at the left end; *c*, the pyloric half of the stomach, exhibiting three dilated parts; *d*, the duodenum. Fig. 6. shews the stomach of the great *kangaroo*: *a* indicates the œsophagus; *b*, the cardiac portion of the stomach, at the left extremity of which are seen two processes, *c* and *d*. At the doubling of the pyloric portion *e*, are also seen two processes like cæca, which are pointed out by the letters *f* and *g*. The pylorus is shewn by the letter *h*. Fig. 7. represents the shape of the digestive organ in the *vampire bat*: *a* is the œsophagus; *b*, the dilated part, by which that tube communicates with the stomach; *c*, the cardiac end of the stomach; *d, d*, the two convolutions of the pyloric portion of the stomach; *e*, the duodenum. Fig. 8. exhibits the external form of the stomach in the *two-toed sloth*: *a* is the œsophagus; *b, b, b*, indicate the elevations upon the surface of the cardiac or first division of the stomach, that are produced by the three cavities into which it is separated internally; *c*, the pyloric portion of the stomach. Fig. 1. Plate III. of the *Anatomy of Mammalia*, represents a view of the first stomach or paunch of the *camel*, laid open on the anterior part to expose its internal structure and communication with the second stomach: *a* is the œsophagus; *b b*, the longitudinal ridge, dividing the cavity into two compartments; *c c*, the muscle which passes to the third stomach; *d*, the opening into the second stomach; *e e*, the muscular cells on the right side of the cavity; *f f*, the larger cells on the left side, the water of which serves to moisten the food lying over them, and to make it of a fit consistence to be regurgitated into the mouth, along the canal formed by the longitudinal ridge, and the muscle going to the third stomach; *g g*, a broad muscular band separating the cellular structure into two portions. Fig. 2, of the same plate, exhibits a posterior view of the four stomachs of the *camel*, in which the first is unopened, but the succeeding three are cut open, and preserved in three relative situations to the first stomach: *a* is the œsophagus; *b b*, point out the posterior surfaces of the first stomach in a distended state; *c* shews the communication between the first and second stomachs; *d d*, the muscle running along its upper part to terminate in the orifice of the third stomach. This muscle, when it acts with its greatest force, brings forward the orifice of the third stomach nearly close to that of the second, and by so doing, shuts up the rows of cells in the lower part of the cavity, so that no part of the solid food can pass into them; *e, e*, the rows of cells which form a reservoir for the water; *f*, the opening leading into the third stomach; *g*, the cavity of that stomach; *h*, the orifice of the fourth stomach; *i i*, the longitudinal plicæ of the fourth stomach; *k k*, the rugous structure at the lower part of the same cavity; *l*, the glandular projections opposed to the orifice of the pylorus; *m*, the pylorus; *n*, the dilatation or membranous cavity between the pylorus and duodenum; *o*, the duodenum.

Fig. 3. Plate III. of the *Anatomy of Mammalia*, is designed to shew the directions of the muscular fibres, which run upon the orifices and sides of the cells in the first and second stomachs of the *camel*. The cells of the left side of the first stomach are employed as examples, on account of their being the largest, and their muscles the most distinct, but the same structure exists in the cells of the second stomach also: *a a*, the longitudinal ridge, to shew its muscular structure, and the mode in which the fibres go off, to furnish the orifices of the cells; *b b b b* point out the course of the fibres going from cell to cell to close their orifices; *c, c*, the muscular fibres, by means of which the cells throw out their contents. In Plate IV. of the *Anatomy of Mammalia*, fig. 1. is a view of the internal surface of the stomach in the *rat*: *a* is the portion of the stomach over which the cuticle of the œsophagus is continued. This cuticular coat terminates in an eminent puckered border; *b*, the pyloric portion of the stomach. This figure is of the natural size.

Fig. 2. of the same plate, exhibits the external appearance of the stomach of the *dormouse* of the natural size, seen posteriorly: *a*, the œsophagus; *b*, the gland, seen full, on account of the curvature which the œsophagus makes before it enters the stomach. Fig. 3. is a view of the cellular structure of the gland, which is exposed by slitting the part open: a portion of the stomach is left with the gland. Fig. 4. shews the stomach of the *wombat*, less than the natural size, and inverted, to expose the internal appearance and foramina of the cardiac gland. The inner surface of the stomach displays some reticulated lines at the great end, from which longitudinal lines are extended towards the pyloric portion of the stomach: *a*, the œsophagus, covered with cuticle; *b*, the gland. Fig. 5, of the same plate, shews the stomach of the *porpoise*, of course much less than natural: *a* is the œsophagus; *b*, the first stomach or reservoir of the food; *c* is the second stomach; *d* is a portion of it, distinguished on this side by a fissure, which some have considered as separating it into a third stomach; *e* is the intestine-shaped stomach, which we are disposed to admit as the beginning of the duodenum; *f* is the last stomach, or, as we suppose, the dilated part of the duodenum for receiving the pancreatic and biliary fluids; *g* is the intestinal canal.

Intestines.—It may be stated as a general observation, from which there are scarcely any exceptions, that the capacity of the alimentary canal is in proportion to the difficulty of assimilating the kind of food used by the animal. It is, therefore, greatest of all in those animals that live upon raw, fibrous, or woody vegetables; less in those that consume succulent or cooked vegetables; less still in those that eat animal food occasionally; and least of all in those that subsist exclusively upon flesh, fowl, and eggs.

It should, however, be remembered, that the length of the intestinal canal by no means determines the extent of the digestive apparatus. The length should always be calculated in reference to the width in general of the intestines; the dilatation of particular parts, and the extension of their internal surfaces by folds or valves. The complication of the stomach, and the perfection of the organs of mastication, should also be considered as influencing any conclusion to be drawn from the length of the intestinal canal.

In the truly *carnivorous mammalia*, the whole tract of the intestines usually exceeds the length of the body, only in the ratio of three, four, or five to one. In the *great bat* (*vespertilio noctula*), the intestines are but twice the length of the animal. The proportion of the circumference to the length of the intestine, in this species of *bat*, is as one to twenty-eight. In the *hyæna*, the intestinal canal is eight times longer than the body, but then the proportion of the cir-

MAMMALIA.

cumference to the length of the small intestine, is as one to one hundred and ten; that of the cæcum as four to nine; and that of the colon and rectum, taken together, as one to six.

In the *human subject*, the length of the intestines is six or seven times that of the body.

In the *monkey tribe*, this proportion varies from five to eight.

In the *lemur genus*, with the exception of the *loris*, the intestines vary from four to six times the length of the body. The *lemurs*, it should be observed, have a larger cæcum than the *monkey* kind. The *loris* have still shorter intestines in proportion to their body; but the latter is very long.

Amongst the *chiropterous mammalia*, the *vampire bat* has the intestine about seven lengths of its body. It has a complicated stomach and no cæcum.

In the greatest number of the *plantigrade* quadrupeds, the intestines have a considerable length. This is counteracted by the smallness of the canal, and the want of a cæcum. The *skunks* have the intestines short, and in other respects like the *carnivorous digitigrade* mammalia.

In the *herbivorous saltigrade*, the length of the alimentary canal is considerable, besides the addition of cæca, but in the *rat* genus, which live on a mixed food, the length of the intestines does not exceed that of the *monkeys*.

The intestines are short in the *edentata*, and very much so in the *tardigrada*, which seems hard to explain, as they want the cæcum, and live, nevertheless, upon vegetable matters. Cuvier supposes that the gastric juice may be particularly active in the *tardigrade* animals.

The *echidna* has the intestines seven times its own length. In the *armadillos* they are only five lengths of the body.

In the *elephant*, the intestinal canal is only seven times as long as the body, but it is very wide. In the *hippopotamus* it is nine times as long as the body. In the *daman* it is about the same.

The *ruminating* quadrupeds have the longest intestinal canal of all. In the *ram* it is twenty-seven lengths of the body.

The *solipeda* have the intestines about eight to ten times as long as the body, but the want of extent is amply made up by the prodigious volume of the cæcum and colon.

The *seal*, although supported by animal food, has the intestinal canal eighteen times as long as its body, the diameter, however, is small, and its stomach is very simple, and its teeth incapable of minutely dividing its food.

The *southern lamantin* (*trichecus australis*) has the intestines only about six lengths of its body, although it lives upon vegetables; but it has a complicated stomach furnished with a large gland.

The *cetacea* have a long alimentary canal, but it is very narrow, and wants the cæcum. In the *grampus* we found the large blood-vessels, as the vena cava and portæ, and the aorta, to be nearly the same width of the intestine.

It is curious to observe the occasional difference between the length of the intestines in the wild and tame species of the same genus. Thus, in the *wild boar*, the body bears the proportion to the intestines of 1 to 9; in the *hog*, of 1 to 13.5; in the *wild cat*, it is as 1 to 3; and in the *domestic cat*, as 1 to 5. This proportion is different in the *wild and tame rabbits*; the former has it as 1 to 11.4, the latter as 1 to 9.3.

Cuvier has given a very full table of the proportionate lengths of the different parts of the alimentary canal, and also of their circumference, in the third volume of the "Anatomie comparée," to which we shall refer the reader.

The length of the whole intestinal canal, in relation to that

of the animal, is greater in mammalia than in the other classes of animals. This unquestionably becomes necessary from the food undergoing a more tedious process of assimilation, but it likewise depends in a degree on the more elongated form of the body. This observation particularly applies to *fishes*, in whom the tail becomes incorporated with the general figure of the animal. To calculate the relation of the intestinal canal to the body, the capacity of the one, in all directions, should be compared with the entire bulk of the other. The length and the width also of the great intestines are greater in proportion to the small intestines of mammalia than in any other class. It is in these animals that the terms of great and small intestines are only indeed appropriate.

The great and small intestines are nearly of the same length in the *saltigrade* quadrupeds; sometimes the former are even longer: for instance, in the *paca*, the length of the small intestines is to that of the great, as 1 to 1.3, and in the *water-rat*, as 1 to 1.2. In the *hamster* and *field rat*, it is, however, in the proportion of 2 to 1, and in the *Norway rat* and *common mouse* the small intestines are four times the length of the great.

In the *hoofed* quadrupeds there is not a great difference between the length of the two divisions of the intestine in general. What there is, however, is in favour of the small intestines, but it should be recollected that the great intestines are commonly wide in these tribes of quadrupeds.

In the *omnivorous* quadrupeds, the small intestines exceed the great in length somewhat more, although the great are not so much dilated as in the *large herbivorous* species.

But it is in the *carnivorous* tribes that the small intestines are very materially longer than the great. Thus, in the *lion* and *jaguara*, they bear the proportion of 6 to 1; in the *dog* and *wolf*, 5 to 1; in the *hyæna*, 6.2 to 1, &c. In some *monkeys*, and in the *human subject*, they are also about 5 to 1, but this is in a degree counteracted by the width of the great intestines.

We shall now proceed to the description of the forms and structure of the intestines in mammalia, which it will be necessary to treat a little in detail.

The intestinal canal of the *monkey* kind approaches in general structure that of the human subject. In the *ourang-outang*, there are both a cæcum and an appendix vermiformis, as in *man*; but in the other species of *monkey* the latter is wanting. The cæcum of the *ourang-outang*, according to the representation given of it in Tyton's Anatomy of the *pigmy*, does not project much out of the line of the intestine; but in the other species of *simia*, the cæcum forms more of a cul-de-sac than in man, except the *gibbon* or *long-armed ape*. The Parisian dissectors describe the cæcum of the *sapajous*, or the subgenus *callitrix*, as being two inches and a half long and one inch wide at the origin, after which it becomes smaller, and ends in a pointed manner. They likewise describe some valves on the inside of the colon of the *sapajous*, similar to those found in the colon of the *ostrich*.

The *lemurs* have the cæcum more elongated than the *monkeys*. In the *lemur macaco*, the colon is much wider in the beginning than the small intestines, but afterwards becomes rather less. The cæcum is wider than the latter at its origin, but becomes gradually smaller at the end. It is a considerable length, and forms many spiral convolutions, and has a good deal the appearance of a coiled worm. In the *tardigrade* and *slender lemurs*, the parietes of the intestinal canal are thin, and dilated at intervals into sacs; the cæcum is long and but little dilated. The *lemur tarsius* of Pallas has the great and small intestines about an equal width,

MAMMALIA.

width, except the cæcum, which is long and prodigiously dilated.

In the *galeopithecus*, the first portion of the colon and the cæcum have three longitudinal bands, which throw them into numerous and regular sacs. This facculated part of the gut is very wide compared with the rest. The small intestine opens into it at a right angle, about half way between the extremity of the cæcum and the termination of the dilated and facculated part of the colon, which is continuous with the cæcum.

The *bats* have the great and small intestines nearly of the same width, and the internal coat has no transverse folds or valvulæ conniventes. It has merely villi on the surface, which decline as usual in the great intestines. They have no cæcum, but sometimes a slight projection at the origin of the colon. The *vampire bat* has the first part of the canal wider than the rest, and with very thin coats. It is more contracted and has thicker coats in the rectum, in which there are also some longitudinal folds internally.

The *carnivorous plantigrade* quadrupeds, except the *ichneumons*, have the intestinal canal nearly of the same width throughout. In general the coats of the rectum are thicker than in the other parts, and there are some longitudinal folds in it. There is no cæcum, but at the part corresponding to it there is a row of mucous glands upon one side of the intestine. The internal coat of the canal is more or less villous in the different genera. In the *mole*, for instance, the villi are short; in the *hedge-hog* they are long in the small intestines. The *ichneumons* have a small process at the origin of the colon, which Cuvier terms a cæcum, but which ought rather, perhaps, to be called an appendix vermiformis. In the figure he has given of this part in the Egyptian *ichneumon*, it appears a good deal less than the small intestine, which is itself not half the diameter of the colon. Hedwig describes the intestines of the *bear* as having long and handsome villi.

Amongst the *digitigrade carnivorous* quadrupeds, the genus *mustela* is distinguished by the want of a cæcum. The *otter* has a slight dilatation at the place where the cæcum might be. The inner membrane is finely villous in the small intestine. This appearance diminishes towards the part of the canal corresponding to the great intestine, and is again to be found near the anus. The row or stripe of mucous glands, which is usually observed to cover a considerable extent of the side of the canal at the origin of the colon, is very striking in this genus.

The other *digitigrade carnivora* have always more or less of cul-de-sac at the origin of the colon. Their great intestines are however short, and without any sacs or dilatations by which the progress of the food is retarded through them. There are, likewise, no valvulæ conniventes in the small intestines, but the inner coat has fine villi. The genus *viverra* has a short slender cæcum, similar to that of the *ichneumon*. The small intestine has an oblique or a valvular opening, and the inner coat exhibits at that place some marked longitudinal folds.

In the genus *felis*, the small intestines have a much less diameter than the others. The villi are very evident, in some species particularly. In the *lion* the villi are long and floating. The cæcum in this genus is short, and terminates in an obtuse cone, of which the coats are thick, and contain many mucous glands. There are some longitudinal rugæ towards the end of the colon, and in the rectum.

In the *dog* kind, the villi of the small intestines are long. The cæcum forms some curves, which adhere to each other, and to the side of the small intestine, by means of the cellular substance, which renders the passage of any substances

through it more difficult. There are some longitudinal folds in the great intestines, as in the *cats*. The whole canal is nearly of the same width.

The coats of the intestinal canal are thin in the *lyena*. Their diameter continues to increase from the pylorus to the cæcum. The latter is long and narrow, and has a rounded termination.

In the *pedimanous* or *marsupial* animals, there is some variety in the intestinal canal. The *Virginian opossum* has the small intestine a third less than the great: they have fine villi interiorly: there are no rugæ or valvulæ. The cæcum is not long, and appears to be a prolongation of the colon. In the *marmoset* or *murine opossum*, the small and great intestines are about the same diameter: they have some contractions. In the *cayopollin*, or *Mexican opossum*, the duodenum is wider than the rest of the small intestines. The cæcum is long, straight, and twisted in a spiral manner. The colon is larger at the origin than elsewhere. The *brown phalanger* (*didelphis orientalis*) has the small intestines one-third less in diameter than the great. The cæcum is very long, wide, and formed into numerous sacculi along the sides, and terminates in a small canal, which Cuvier considers a species of appendix vermiformis.

In the *kangaroo rat*, the coats of the intestines are thin. The small guts have the internal membrane without villi, but it is thrown into very fine folds, which form zig-zags transversely: the cæcum is short, wide, and round. The colon is very large at its origin.

In the large *kangaroo* the intestinal canal differs very much from that of the preceding species. The diameters of the small intestines diminish gradually from the duodenum to the ileum. Their inner surface is without rugæ, but is villous. The cæcum is capacious, very long, and is facculated by two longitudinal bands, which also extend for some way upon the colon, producing the same effect upon it. The great intestine afterwards becomes narrow. The facculated portion of the colon has irregular folds internally, and there are some slight longitudinal rugæ in the remainder of the great gut. The intestines of the *kangaroo* resemble those of the *saltigrade* quadrupeds, in which tribe we have placed it in our classification.

In the *phascolumys*, or *marsupial rat* of New Holland, which also should be classed with the *saltigrade* quadrupeds, the whole tract of the intestines, even the cæcum, is nearly of the same width. The cæcum is short, round, and smooth: there is an appendix vermiformis which goes off at the angle formed by the small intestine with the cæcum. It has a small orifice guarded by a valve. The *phascolumys* and the *ourang-outangs* are the only instances in mammalia which have both a cæcum and vermiform appendix: in this circumstance they resemble the human subject.

The *porcupine* has the duodenum very wide, somewhat resembling an additional stomach. The remainder of the small intestines is narrow. The villi of the mucous membrane have the figure of thin conical scales, as in the human intestine, but more narrow and prominent. The cæcum is large, divided into sacs by three muscular bands. At the origin of this intestine, there is one of those sacs much larger than the rest, projecting out of the line formed by the colon with the cæcum. This gut altogether has a good deal the figure of a scythe. The colon has some cells of a smaller size than those of the cæcum.

In the *guinea-pig* the cæcum is very capacious, and is in a degree coiled when it gives origin to the colon, which is almost as wide as the cæcum for a little way, but afterwards gradually contracts to the dimensions of the small intestine.

MAMMALIA.

The *paca* and *agouti* resemble the *guinea-pig*. The opening from the cæcum in these animals is contracted by a valve. The colon of the *agouti* forms behind the liver many little concentric convolutions before it terminates in the rectum. The glands at the origin of the colon are very remarkable in the *paca*, forming a thick mass.

In the *rabbit* and *hare* the small intestines are uniform in their size. They are villous, and have some longitudinal folds internally in the ileum. The cæcum is very extensive. It has a conical figure, and exhibits regular contractions upon the surface, which correspond to a spiral fold that interrupts the cavity internally, like the spiral valve in the cæca of the *ostrich*. The colon is as wide as the cæcum at its origin, but it very soon contracts: it is facculated at first by three longitudinal bands, and afterwards by only one. The internal coat is smooth in the cæcum, papillated in the first portion of the colon, and longitudinally rugous in the rectum.

The *squirrel* has a long cylindrical cæcum with smooth parietes. The *flying squirrel* has a similar intestinal canal, but the cæcum ends in a pointed manner.

The *beaver* has a short dilatation at the origin of the duodenum. The cæcum is of great size, elongated, and conic. The colon also is very wide at its origin. There are numerous contractions and dilatations throughout the great guts.

The *Polish marmot* has the small intestines straight. The cæcum is very voluminous, and divided externally by contractions, and internally by a corresponding number of annular folds. The colon is large at the beginning. The intestines of the *marmot* of the Alps are similar to the preceding.

In the *ondatra*, or *musk rat*, the cæcum is of a prodigious extent: it passes from the umbilical region to the left iliac; then into the right iliac, extending as far as the hypochondriac region of that side. The colon at its commencement is convoluted in a spiral manner.

The greatest part of the intestinal canal of the *water-rat* has a small diameter. The cæcum is long and wide, with contractions. The colon is very wide at its origin; it diminishes afterwards, and is twisted in a close spiral manner for a great part of its length. The twisted part of the colon is distinguished by regular folds, which are visible from the outside of the gut. The coats of the whole intestinal canal are thin and transparent in this animal.

The intestinal canal in the *campagnol* (*mus arvalis*) resembles that of the *water-rat*.

The cæcum is wide, short, a little curved, and without contractions, in the *black* and *Norway rats*; longer and narrower in the *common mouse*; elongated also, tapering at its extremity, and divided by contractions in the *field rat*. In the *Norway* and *black rat* the colon is at first straight, has thick coats, and some longitudinal folds interiorly; after which it is dilated, and exhibits, for some way, similar spiral traces to those of the *water-rat*: it then contracts again, and has but a small diameter in the greatest part of its extent towards the anus.

In the *mouse* and *field rat* the colon is wide at the commencement, but afterwards it becomes much contracted. There are oblique or spiral striæ, formed by the folds of the internal membrane.

The *hamster* has the small and great intestines of the same diameter, except where the cæcum is formed. Both the ileum and colon open into a dilated part, which produces at one side several spiral turns, and at the other the cæcum. This last is of considerable size, and divided into a number

of sacs by means of one band or cord, which runs along the concave side of this gut.

In the *mole rats* the cæcum is long and wide, and the colon spirally twisted. The *jerboa* has the cæcum formed into three spiral turns.

Amongst the *edentata* there is a good deal of variety to be observed.

In the *three-toed ant-eater* the small intestines are very much puckered by the mesentery, by which the canal is irregularly contracted and dilated, like the great intestines of many animals. The large intestines of this animal form a short, wide, smooth canal; and on each side of the termination of the ileum in this great gut, there is a little process or appendix, with a contracted neck and bulbous head. These appendices correspond in situation to the cæca of birds, with which class of animals the toothless quadrupeds are allied in many parts of their structure and economy. The cæca of the *ant-eaters* are too small to serve as reservoirs for their food: they communicate with the great intestine by a small orifice, as does also the ileum.

In the *echidna* the small intestines are about half the width of the great: they have villi, but no valves upon the interior surface. The mucous glands are numerous, and particularly plain from being of a black colour. The cæcum is single: it is a short, straight, blunt process.

In the *ornithorhynchus* the duodenum is wider than the rest of the intestinal canal, which gradually diminishes to the cæcum. This part is a long narrow process or appendix. The great intestines grow wider the nearer they approach the anus. The internal membrane in the small intestines is formed into numerous prominent laminae, somewhat like those of fishes; and in the beginning of the great intestines it produces some longitudinal folds.

The *long-tailed manis* has no cæcum: the commencement of the colon is distinguished by an increase in the width of the intestine, and the thickness of its coats. There is no cæcum likewise in the *pangolin*, or *short-tailed manis*.

There is no cæcum in the *armadillos*, but the great intestine is thicker and wider than the rest of the canal, from which it is separated by a contraction: the small intestines are much puckered and folded by the manner in which the mesentery is attached to them.

The *tardigrade* quadrupeds have the small intestine gathered into irregular dilatations by the mesentery. There is no cæcum. The great intestine is distinguished from the small by a sudden dilatation, and a valve interiorly at the part where the colon commences. The irregular form and contractions of the small intestines, in some of those animals which have the colon short, and want the cæcum, are designed apparently to answer the same purposes that a capacity in the great intestines does in other animals.

The *Cape ant-eater* has a short oval cæcum.

The *hoofed quadrupeds* are remarkable for the capacity of their great intestines. Amongst the *multungulata*, the *elephant* has the colon so large as to cover a great part of the abdominal viscera: it is folded from side to side, and lies in the front of the other intestines: it is facculated in two rows on each side. The cæcum is also very large, and thrown into sacs or cells by three muscular bands. The small intestines have an uniform diameter. The ileum terminates by a circular valvular opening in the colon. The internal membrane of both the small intestines and the colon is plicated transversely: in some places it projects so as to form valves; in the rectum the folds are longitudinal. The surface of the internal membrane in the small intestines is covered with fine short papillæ. The coats, more particularly the muscular one, are very thick.

MAMMALIA.

In the *one-horned rhinoceros* the cæcum is very wide, and divided into sacs, as is the colon still more plainly, at least at one part; but the most curious part of the structure of the intestinal canal in this animal is to be observed in the inner coat. In the first portion of that part of the canal between the pylorus and the insertions of the hepatic and pancreatic ducts, the mucous membrane forms little projecting longitudinal folds, in the form of segments of a circle: in the next portion of the same part of the gut, these folds become more transverse in their direction, and assume a triangular figure. A little beyond the insertion of the biliary ducts the laminae become more numerous, compressed, and irregularly lobed. Farther on there is upon the internal coat a kind of papillæ, lengthened into filaments, pressed the one against the other, especially about the middle of the length of the small intestine. The extremities of some of these processes are bifid. The internal surface of the cæcum has only the rugæ that correspond to the sacs. The laminated structure is renewed in the colon; the folds are transverse, and grow larger as they come nearer to the rectum, between which gut and the colon the last lamina forms a valve.

The *Cape cavy* has very singularly formed cæcum and colon: the first of these is a large irregularly shaped bag, which is puckered upon the sides by two longitudinal bands. The ileum opens into it by a projecting contracted orifice, and near the same place the colon arises: there is a valvular fold at the aperture of the colon. This intestine is at first suddenly and greatly dilated: the inner coat of this portion is smooth, and irregularly plaited, as in the cæcum. The part of the canal succeeding the dilatation is small, has thick parietes, and the inner coat with waving folds, which are at first longitudinal, but afterwards become transverse in their direction. Beyond this portion the colon grows wider, and then becomes irregular in its shape and diameter: it has broad longitudinal folds internally. There next succeeds another enlargement of the colon, from the sides of which arise two pyramidal or cone-shaped processes, which pass in the direction contrary to that of the rest of the gut, in the same manner as the cæca of birds, to which they bear a considerable resemblance. The colon, after furnishing these two appendices, makes several spiral turns upon itself, and some convolutions in the belly, and terminates in the rectum. This last intestine has thicker coats than the colon, and has broad longitudinal folds internally.

Amongst the *bisulca*, the *ox* has no folds in the interior of the small guts, except in the duodenum, where there are some transverse rugæ or plaits. The villi have the figure of fine scales, according to Cuvier; but we may observe, this structure is by no means uncommon in mammalia. The cæcum is not large: it is first contracted, then dilated, and terminates in a bulb. The inner coat is without rugæ, except where it is narrow, and there we find some longitudinal rugæ: the colon is without folds of the inner coat: the rectum has thicker coats; and the internal surface furnishes longitudinal folds, and, very near the anus, some circular ones. The *goat* has a much larger cæcum in proportion than the *ox*.

The duodenum of the *lama* is wide at the commencement, forming an oval sac; the other small intestines are puckered by the mesentery. The cæcum has a conical shape, and no contractions: the internal membrane of the small intestines has some transverse folds; that of the colon longitudinal ones. In other respects the intestinal canal of the *lama* resembles that of the *ox*, as does also the alimentary canal of the other *ruminants without horns*.

The great intestines are much more capacious in the *horse*, *ass*, &c. than in the *ruminating* quadrupeds; more particularly the cæcum, which is of a prodigious size. This gut is nearly as wide as it is long; and when the excrementitious parts of the food are allowed to accumulate in it and the colon, the abdomen has that tumid appearance which is seen in *asses* and in *horses*, that are fed only upon hay or straw. The colon begins with a dilatation, not much inferior in size to the cæcum: it is doubled upon itself, and in its course through the abdomen it forms other curves or arches. The great intestines are drawn up into sacs: these are larger in the first portions of the colon. For a more detailed account of the intestines of the *horse*, we shall refer the reader to the anatomy of that animal in this dictionary.

It is said, that in the *morse* (*trichecus rosmarus*) the cæcum is situated in the left side of the abdomen. There is no other instance of the kind in mammalia, except in cases of transposition of the viscera. The cæcum in this animal is very inconsiderable, resembling a mere knob of the intestine. Both the small and great intestines have very nearly the same diameter.

In the *southern lamantin* the cæcum has a very peculiar figure: it forms the segment of the outside of a circle, or has a crescentic appearance. The ileum communicates with the middle, from which also the colon arises. This intestine is wider at first than the cæcum, and forms some close convolutions; it afterwards proceeds as a slightly twisted canal, and becomes again enlarged near the rectum, which last gut is wider than the colon.

The *cetacea* are stated by Cuvier to want the cæcum; Hunter, however, asserts that it exists in the *piked* and *large whale-bone whales*. In the genus *delphinus* there is certainly no dilatation corresponding to the cæcum: the last intestines are distinguished by their having a smaller diameter, and thicker muscular coats. In the *porpoise* the internal membrane forms some longitudinal folds, which are not very eminent in the small intestines, and decline in the colon and the rectum. The *grampus* has transverse and longitudinal folds, which produce in some degree the appearance of meshes: these are most plain in the duodenum, and gradually diminish until they disappear. For about ten inches above the anus, the intestine is lined with a thick white cuticle. All the *cetacea*, we believe, have the termination of the rectum covered with cuticle, and contracted in size. In the *piked whale* the inner coat of the duodenum has longitudinal rugæ, at a distance from each other, which receive lateral folds: these decline in the other intestines, and appear to correspond with the meshes of the *grampus*. The duodenum in the *bottle-nose whale* swells into a large cavity, which might be called an additional stomach, if it were not that the hepatic ducts terminated in it. The whole of the intestinal canal in this species nearly has the inner coat forming sacs or cells, which are again subdivided into smaller cells. These open, or have their mouths directed towards the anus, or in the course of the food through the canal.

The *cetacea*, as also all other animals that inhabit exclusively the water, never have any flatus in their intestines. The *spermaceti whale*, however, produces a curious excrement, which is called *ambergris*. This substance is sometimes found floating on the surface of the seas that are frequented by these *whales*, and at others is taken from their great intestines. When *whales* are in a healthy state, their excrements are liquid, and of a black colour; but when sickly, the fæces are solid, and accumulate in such quantity in the intestines as to produce a tumour of the abdomen. It is in these cases that the *ambergris* is obtained from the
whales

MAMMALIA.

whales themselves: it is found in the great intestines, about from two to six or seven feet from the anus. When taken out, it has the same smell and the black colour of the fluid fæces; but after exposure to the air, it becomes harder, whiter, and acquires its peculiar odour. The pieces of ambergris are of various sizes, from half an ounce weight to 100 lbs. or more. Dr. Swediaur relates that one piece weighed 182 lbs., and another 130 lbs., which was worth 500*l.* The ambergris is found largest and purest in the *male whales*. Mr. Hornby found that human fæces, by being long digested, acquired so strong a smell of ambergris, that the vessel was obliged to be removed out of the laboratory.

Plate V. of the *Anatomy of Mammalia*, represents the most remarkable varieties in the form of the intestines. Fig. 1. is the cæcum and appendix vermiformis of the *ourang-outang*: *a* is the ileum; *b*, the cul-de-sac, which takes the place of cæcum; *c*, the colon; *d*, the appendix vermiformis. Fig. 2. shews the same parts in the *phascolumys*. The appendix is seen to communicate with the gut by a valvular opening. Fig. 3. is the origin of the great intestines in the *lemur macaco*: *a* is the small intestine; *b*, the colon; *c* is the long convoluted vermiform process, corresponding to the cæcum. Fig. 4. is taken from the *ornithorhynchus paradoxus*: *a*, the small intestine; *b*, the colon; *c*, the straight appendix, which has been considered analogous to the vermiform. Upon the same side of the gut a number of black specks are visible, which are produced by the mucous glands, they appearing of a dark colour in this animal. Fig. 5. exhibits the cæcum and parts adjacent in the rabbit: *a*, the small intestine; *b*, the cæcum; *c*, the colon. The figure being drawn from a dried preparation, the course of the spiral membrane is seen through the coats of the great intestines. Fig. 6. represents some coils of the small intestine, and the commencement of the great intestine, with a portion of the latter in the *three-toed ant-eater*: *a*, the small intestine, very irregularly formed; *b*, the great intestine; *c, c*, the two curious cæca peculiar to this animal. Fig. 7. is intended to shew the cæcum in the *Cape cavy*: *a* is the ileum; *b*, the sac, corresponding to cæcum from which the colon arises; *c*, the colon doubled upon itself at its origin. Fig. 8. represents the two additional processes which are produced by the great intestine of this animal: *a, a*, are some of the spiral turns of the colon at this place; *b, b*, the two sharp processes, resembling the cæca of birds; *c*, the continuation of the gut, after it has furnished these two cæca.

Liver.—This viscus is, in proportion, rather less bulky generally in mammalia than it is in man. It is usually divided more deeply into lobes, and these are also, in many species, more numerous. The division of the liver into several, almost distinct lobes, has been chiefly observed in the beasts of prey, and an opinion has been entertained by some, which was first advanced, we believe, by Monroe, that it was necessary, on account of the sudden and extensive flexions of the spine in these animals when running. Cuvier has inserted the number of lobes that are found in a great many species, from which we have composed the following table.

Animals.	No. of Lobes in the Liver.
<i>Ourang-outang</i>	Two large and one small, as in man.
<i>Simia paniscus</i>	Five.
<i>S. pates</i>	Three.
<i>S. subca</i>	Three.

Animals.	No. of Lobes in the Liver.
<i>Simia cynomolgus</i>	Four large and one small.
<i>Howling monkey</i>	Four.
<i>Lemur macaco</i>	Two large and one small.
<i>L. mongooz</i>	The same.
<i>L. tardigradus</i>	Four unequal size.
<i>L. tarsius</i>	Three large and one small.
<i>L. catta</i>	Two large and one small.
<i>Galeopithecus variegatus</i>	Two, the left is again subdivided into five lobes.
<i>Vampyre bat</i>	Four large and one small.
<i>The other bats</i>	Three.
<i>Brown bear</i>	
<i>Racoon</i>	
<i>Coati</i>	Five.
<i>Hedge-hog</i>	
<i>Badger</i>	Four.
<i>Mole</i>	Three.
<i>Water sbrew</i>	
<i>Otter</i>	Five.
<i>Weazels</i>	
<i>Cat genus</i>	Five to seven generally.
<i>Jaguar</i>	Four.
<i>Lynx</i>	Eight.
<i>Dog kind</i>	Five, sometimes six.
<i>Musk animal (viverra zibetha)</i>	Four.
<i>Viverra genetta</i>	Five.
<i>Opissums</i>	Three to four.
<i>Porcupine</i>	Four large and three small.
<i>Ditto of Hudson's Bay</i>	Four large and two small.
<i>Hare</i>	Three large and two small.
<i>Pika</i>	
<i>Lepus tolai</i> of Pallas	Five.
<i>Lepus ogotona</i>	Seven.
<i>Beaver</i>	Four.
<i>Paca</i>	
<i>Agouti</i>	Three large and one small.
<i>Cavy</i>	Four.
<i>Guinea-pig</i>	Two large and one small.
<i>Common Squirrel</i>	Five.
<i>Palm Squirrel</i>	Three.
<i>Flying Squirrels</i>	Five.
<i>Bobac</i>	Three.
<i>Marmot</i>	Five.
<i>Water rat</i>	
<i>Short-tailed rat (M. arvalis)</i>	
<i>Hamster</i>	Six.
<i>Black and Norway rats</i>	
<i>Mouse</i>	
<i>Sand rat</i>	
<i>Lenming, or Lapland marmot</i>	Four great and one little.
<i>Mus lagurus</i>	
<i>Mus agrarius</i>	Three.
<i>M. aconomus</i>	Seven.
<i>Dormouse</i>	Five.
<i>Ondatra, or musk rat</i>	Four.
<i>Kangaroo</i>	Five large and one small.
<i>Phascolumys</i>	Four.
<i>Ant-eaters</i>	Three.
<i>Ornithorhynchus</i>	Three large and two small.
<i>Echidna</i>	Four.
<i>Armadillo</i>	
<i>Orycteropus</i>	Three.
<i>Hog</i>	
<i>Pecari</i>	Four.

Elephant

MAMMALIA.

Animals.	No. of Lobes in the Liver.
<i>Elephant</i>	} The two lobes have only two notches.
<i>Rhinoceros</i>	
<i>Horse</i>	
<i>Stag</i>	
<i>Antelope</i>	
<i>Dolphin</i>	
<i>Porpoise</i>	
<i>Gazelle</i>	} Three.
<i>Chamois</i>	
<i>Ram</i>	
<i>Goat</i>	
<i>Seal</i>	Six.
<i>Northern lamantin</i>	Two large and one small.
<i>Whales</i>	Two large and one small.
<i>Ruminants without horns</i>	} Resemble the human subject.

The lobes of the liver in mammalia, from being more distinct, are thinner in their form, and have sharper edges than in the human subject. Differences in the figure of this viscus are, however, immaterial, as they do not affect its functions.

The intimate structure of the liver is essentially the same in man and mammalia. The last branches of the vena portæ terminate in both in the same manner, and give origin to the excretory ducts.

The chief varieties in the biliary system of mammalia are produced by the number and situation of the trunks of the hepatic ducts, and the absence of the gall-bag.

The gall-bag is not found in the following instances; viz. many of the *saligrade* order, as the *common rats* and *mouse*; the *hamster*, the *mus talpinus*, *mus minutus*, *mus agrarius*, *mus sngarus*, *mus phæus*, *mus arenarius*, *mus acedula*; in the *Hudson's Bay porcupine* (*hystrix dorseta*); all the *tardigrade mammalia*; amongst the *many-hoofed quadrupeds*, the *elephant*, the *rhinoceros*, the *daman*, and the *pecari*. Of the *ruminants*, the *camel*, *dromedary*, and *stag*; all the *solipeda*; the *northern lamantia*; and the *cetacea*, according to Hunter, although Cuvier only states the *porpoise* and *dolphin* as wanting the gall-bag.

In some mammalia there is a dilatation in the course of the bile to the intestine, which may answer some of the purposes of the gall-bag. This dilated part is most remarkable in the *elephant*, on account of the numerous divisions in it. Upon the biliary duct entering the coats of the duodenum, it becomes enlarged into an oval sac, which is irregularly divided interiorly: some of the septa are placed nearly transversely, but in such a manner as to produce the effect of a spiral valve. They create four principal apartments: two other septa placed at the separation of the first, in the longitudinal direction, form as many more pouches. There is at last a small cell which precedes the four principal ones, and which opens into the first of these. It receives the orifice of the pancreatic duct upon its side, and that of the biliary duct in the direction of its axis. This reservoir of the bile and pancreatic juice opens into the intestine by a moderately small orifice.

In the *horse*, the *ass*, &c. the biliary duct becomes very much dilated before it reaches the duodenum.

In the *northern lamantin* the hepatic duct likewise is greatly enlarged, and receives the pancreatic duct before it passes into the intestine.

We have observed that the biliary duct of the *grampus* enlarges, before its termination, in what has been called the fifth stomach. The same has been noticed by Hunter in the *cetacea* generally.

VOL. XXII.

There are sometimes dilatations of the common duct of the liver and of the gall-bag, even when the latter organ exists. In the *cat* genus, the ductus communis choledochus forms, in the parietes of the duodenum, a sac, which is divided by a membranous septum into two cavities, one of which receives the pancreatic duct.

In the *otter*, the common duct swells into an oval sac on the outside of the duodenum, and becomes contracted again to the original size before it penetrates the intestine.

In the *kangaroo*, the common biliary duct of the liver and gall-bag is large, and joined to the pancreatic before it reaches the duodenum. It is described by Cuvier as having thick glandular coats, and being furnished with strong bands internally, which render its inner surface cavernous. The cells thus produced are deep, and have their mouths directed towards the intestine. The pancreatic duct, although conjoined for a certain distance with the other, is smooth internally. The orifice of these ducts in the duodenum has neither dilatation nor valve.

The situation of the gall-bag, with respect to the liver, appears to be the same in all mammalia. In some species, however, it is more imbedded into the substance of that viscus than in others. Cuvier states, that the gall-bag of the *opossum* is buried as far as the $\frac{2}{3}$ ths of its surface in the parenchyma of the liver.

The figure of the gall-bag is most commonly pyriform. Cuvier states it to be elongated, and approaching a cylindrical shape in the *badger*, *coati*, *otter*, *weasels*, and *civet*. Although, in some others of the same order, it tends to a round figure, as in the *bear*, *hedge-hog*, *mole*, and *raccoon*. It is also round in many *bats*.

The size of the bag varies also in animals that are allied to each other in other parts of their anatomy. Thus, it is large in the *bear*, *coati*, and *hedge-hog*, and small in the *mole*, *porcupine*, &c.

The ducts which carry the bile from the liver, form a greater number of trunks on the outside of that viscus in many mammalia than in the human subject. This appears to be the necessary consequence of the division of the liver into a greater number of lobes than exist in man. In several mammalia these trunks do not unite to form a single duct, but communicate separately with the cystic duct.

In the *monkeys with prehensile tails*, the hepatic ducts form three trunks, which open in succession in the cystic duct, and the ductus communis choledochus appears to be the continuation of the latter; although, in the human subject, the common duct is evidently, both in direction and structure, the continuation of the hepatic duct.

In the *lemur tarsus*, there are also three hepatic ducts which unite with the cystic, in order to form a ductus communis.

In the *variegated flying lemur* there are several hepatic ducts, terminating in the cystic ducts.

The *mole* has two hepatic ducts; one, which comes from the middle lobe, receives the cystic duct. The two hepatic ducts afterward unite to form a ductus communis.

The *hedge-hog* has several ducts from the liver that join with the cystic.

In the *cat kind*, there are many hepatic ducts united to the cystic duct, which is small. The ductus communis undergoes, in the parietes of the duodenum, the dilatation already described.

In the *dog genus*, the hepatic duct opens into the cystic, near the neck of the gall-bag.

The *armadillos* and *ant-eaters* have one trunk from the liver, which joins the cystic at a very acute angle. The common duct is the continuation of the hepatic.

MAMMALIA.

In the *echidna* there are three hepatic ducts joined to the cystic, near the neck of the gall-bag. The cystic is large, and appears to form the ductus communis.

In the *ornithorhynchus* there are two hepatic ducts which end in the cystic in the same manner.

The *elephant* has nine or ten branches from the liver: these form three trunks, which unite again, and make but one. It is inserted into the duodenum, and there suffers the remarkable dilatation previously described.

In the *seal* one hepatic duct joins the cystic near the neck of the bladder, the other at some distance from it.

In some species the hepatic ducts terminate directly in the body or neck of the gall-bag. This has been particularly remarked in the *ox* and *sheep*, in which animals there are several short ducts leading from the liver chiefly into the neck of the gall-bag, resembling what is found in some fishes. A similar structure has also been described in the *wolf*, *dog*, *hedge-hog*, and *hare*; but in these animals the hepatic ducts rather should be considered perhaps as entering the origin of the cystic duct than the gall-bag itself. In the *vampire bat* there is but one hepatic duct. It terminates in the commencement of the cystic. In all these cases the cystic duct must be considered as supplying the place of the ductus communis choledochus. The design of the hepatic ducts opening into the body or neck of the gall-bag, is obviously to produce a more concentrated state of the bile by retarding its progress into the intestine; but it is difficult to explain why this effect should be necessary to animals in whom the organs of digestion, and the quality of the food are so very different.

The existence of a gall-bag, whether the bile be conveyed directly into it, or by regurgitation through the same duct that carries the cystic bile out again, has necessarily the consequence of increasing the peculiar properties of the bilious fluid; it being found that all secretions, when accumulated in reservoirs, become more concentrated by having their aqueous parts absorbed. It would seem that the presence of cystic bile is required more especially to carnivorous animals that have a rapid digestion, as the gall-bag is only wanting in vegetable eaters, if we except the *cetacea*.

The distance from the pylorus at which the bile is poured into the intestine, was formerly considered as determining the digestive powers of the animal, it being supposed that the biliary duct opened nearest the pylorus in the most carnivorous quadrupeds. A further knowledge of comparative anatomy has shewn that no general conclusion of this kind can be drawn. There is great variety, even amongst animals nearly allied in other circumstances, with respect to the situation of the orifice of the biliary duct in the duodenum. Cuvier states that it is nearer the pylorus in the *saltigrade* quadrupeds generally, than in other mammalia, and at the same time the farthest removed in the *kangaroo*, which belongs to the same order.

In Plate VI. of the *Anatomy of Mammalia*, fig. 1. represents the sac into which the biliary and pancreatic fluids are poured in the *elephant*: *a* is the hepatic duct, formed by two branches, which are composed of nine or ten lesser ones; *b*, the pancreatic duct which passes to the cellular receptacle of the bile; *c* is that receptacle laid open, in the cavity of which the septa and apartments already described are to be perceived; *d*, the parietes of the duodenum. Fig. 2. exhibits the receptacle of the bile and pancreatic fluids in the *atter*: *a*, the biliary duct; *b*, the pancreatic duct; *c*, the external form of the receptacle; *d*, a portion of the duodenum.

Pancreas.—In most mammalia this viscus has lobes,

branches, or processes, which make its form different from that of the human subject.

In the *ourang-outang* the pancreas resembles, in its figure, the same gland in man. It has an irregular form in the *Barbary ape*. In the other *monkeys*, the end towards the right side is divided into several processes.

In the *mole*, *hedge hog*, *raccoon*, and *bear*, there are two branches or processes in the right end of the pancreas. The *badger* has it bent into an arch. In the *sbrew*, the left end is separated into two forked processes.

The *cat* genus has the pancreas composed of two irregular shaped lobes, the smaller one accompanies the duodenum from before backwards. The larger lobe is situated transversely. The *dog* has the gland formed nearly in the same way. The *martin* (*musfela foina*) has the pancreas doubled upon itself, so as to resemble, according to Cuvier, an overthrown figure of 6, thus ∞ . In the *viverra gazetta*, and *viverra zibethica*, this gland is a thick, compact, broad band, which reaches from the duodenum to the spleen.

In the *beaver*, the pancreas is long and thin, and accompanies the convolutions of the duodenum. In the *water rat* the pancreas has three long thin branches.

The *echidna* has several branches or processes.

The pancreas of the *elephant* is long and narrow, and without any offsets; it is said to be $6\frac{1}{2}$ feet long.

In the *ox* this gland has the figure of a lozenge.

The pancreas of the *horse* has an irregular figure, and three processes.

In the *seal* the pancreas has distinct lobes.

The *northern lamantin* has two branches to the pancreas.

In the *cetacea*, at least the genus *delphinus*, there is an irregular shaped pancreas, consisting of some roundish lobes massed together. The gland is small, in proportion to the size of the animals.

However the form of this gland may differ in the various genera of mammalia, the organization is uniformly the same in all, and does not differ from that of the human pancreas.

As the pancreas of mammalia has frequently branches or lobes, the excretory duct is often found made up of several others.

The *ourang-outang* has the duct formed as in man, and ending in common with the ductus communis choledochus. The pancreatic and biliary ducts are in the other *monkeys* united in some species, and distinct in others.

The *dog* has commonly two pancreatic ducts, one unites with the common biliary duct, and the other passes into the duodenum, a little distance farther on. In the *cat*, the biliary and pancreatic ducts enter together. The *panther* has them separate, and the duct of the pancreas penetrates the intestine after the other. The biliary and pancreatic ducts unite, however, generally in the *carnivorous* quadrupeds.

They are distinct in the *porcupine*, and enter the intestine at some distance from each other. They are also remote in the *hare*. In the *marmot* the ducts are separate, but enter the intestine near each other. The *flying squirrel*, *kangaroo*, and many other *saltigrade* mammalia, have but one orifice for the biliary and pancreatic ducts.

In the *elephant* the pancreatic duct has two principal branches, one opens into the beginning of the dilated part of the biliary duct, and the other passes into the duodenum at a little distance.

In the *cloven-footed* quadrupeds the biliary and pancreatic ducts are commonly united.

In the *horse* they are separate, although close to each other.

MAMMALIA.

In the *northern lamantin*, and in the genus *delphinus*, these ducts are united.

If one may judge from the variety that is to be observed, with respect to the insertion of the biliary and pancreatic ducts, both as to their conjunction, and the distance of their orifices from the pylorus; these circumstances are unimportant in themselves, and have very little concern with the functions of the pancreas or liver.

In *fig. 5. Plate IV. of the Anatomy of Mammalia*, the letter *b* indicates the pancreas of the *porpoise*. In *Plate VI. fig. 3.* exhibits the curious form of the pancreas in the *martin (musfela foina)*.

Spleen.—The situation of this organ is as nearly as possible the same in all mammalia. It is always attached to the great or left end of the stomach, when the latter is a simple cavity; and when it is composed of more than one cavity, the spleen is connected with the first stomach, or that in which the œsophagus terminates. Thus, in the *ruminating quadrupeds*, the spleen is placed on the left side of the paunch, and in the *estacea* upon the first cavity, or that which is the receptacle of the food in those animals. It is retained in its situation by reflexions of its peritoneal coat, and is likewise connected by its blood-vessels with those of the first cavity, or of the great end of the stomach.

The form of the spleen is very various, and is likewise subject to a change of bulk, and, in a degree, of figure, according to the different states of the distension or fulness of the stomach; it being well known that the spleen, from its spongy structure, is easily compressed by the adjoining viscera.

Cuvier has inserted the figure of the spleen, as he found it in several species. We shall extract the following from his “*Anatomie comparée.*”

The *monkey* kind differ much with respect to the shape of this organ; thus it is triangular in the *long-armed ape*, the *ribbed-nose ape*, the *baboon*, the *simia apella*, the *orange ape*, and the *foujou*, &c. It is broad posteriorly, and divided into two lobes in the *Chinese ape*, and *Barbary ape*. It is long and narrow in the *weeping monkey*, and in the *ring-tailed macaco*, the *lemur mongoz*, and the *lemur macaco*. It is broader posteriorly than before in the *tardigrade lemur*. It is very long, and has the figure of a triangular prism, in the *howling baboon*. In the *lemur tarsius*, the spleen has the shape of an irregular leaf, notched upon the edges.

The *carnivorous quadrupeds* generally have this viscus long and narrow, prismatic or flattened. It has a similar form in the *bats*, the *mole*, *chrysochloris*, *hedge hog*, &c.

In the *galeopithecus variegatus*, and *Virginian opossum*, it is triangular. In the *brown phalanger* it is in three lobes, and has a similar figure in the *Mexican opossum*, and the *marmose (didelphis murina)*.

The spleen is large and oval in the *weasel*.

This organ is triangular, broad, and flat, in the *kangaroo rat*, *water rat*, and *guinea-pig*. Very long, narrow, and thin in the *great kangaroo*; long and narrow in the *marmot*, *common rats*, and *bare*. The figure of the spleen is said to vary in different individuals of the *porcupine*.

The *echidna* has three branches to the spleen. It is larger than the stomach in the *ornithorhynchus*, and square.

The spleen is very long in the *elephant* and *hog*; broad and flat in the *rhinoceros*; of a femilunar form in the *damian*.

It is round and flat in the *stag*; thin and oval in the *gazelle*; flat, large, and femilunar in the *lama*. It is broad and thin in most of the other *ruminating quadrupeds*.

The *horse* has a flat triangular spleen.

The most remarkable deviation of structure is found in the *estacea*. The *porpoise* and *dolphin* have, according to Cuvier,

seven small round spleens of various sizes, from the bulk of a chestnut to that of a grain of corn. We have counted but five spleens in the *porpoise*. It is probable they vary both in number and size. They are scattered over the first stomach in the course of its blood-vessels, from which they receive their branches. In the *grampus* we did not observe these small spleens, but found a long stripe of a spongy substance, which appeared to be the spleen. We do not wish, however, to speak positively, as it was paler and closer in its texture than the spleens of other animals, and the parts surrounding it were so much injured in being taken out of the animal, that we could not satisfactorily make out their connections. This stripe was two feet long, and about one inch broad for its greatest extent. Towards the root it becomes gradually wider, and where it appears to originate, it is three inches broad. Hunter states the spleen in the *whales* to be very small.

The variations as to bulk are not very material in the spleens of mammalia; the *herbivorous quadrupeds* appear to have the organ largest, and perhaps the *estacea* should be considered as having the smallest spleen.

The colour of this viscus is generally deeper in mammalia than in the human subject.

No satisfactory account has yet been published of the intimate texture of the spleen in mammalia. As far as our observation extends, the organization is essentially the same in this class of animals as in man. In the spleen of the *ox*, *sheep*, *horse*, and *hog*, &c. the cellular structure described by Malpighi and Stukely is more apparent than in man, or the small quadrupeds; and the ramification of the blood-vessels upon these cells is discoverable. Mr. Home relates, that he saw these cells very distinctly when in a distended state. He says that the roots of the splenic vein arise from the outside of the cells at right angles to their circumference, like radii. When the injection has not been very minute, they are seen to arise at so many points of the capsule; but when the injection has got into smaller branches, their number is so much increased, that they appear to form plexuses round the cells. Mr. Home also found invariably that the grains described as glands by Malpighi, and called corpuscles by Cuvier, are distinct cells, which contain a fluid, when the stomach had received an unusual quantity of liquids. This fluid was evacuated by puncturing the cells when their membranous coat became visible. Mr. Home further ascertained, that the trunk of the splenic vein, compared with that of the artery, was in the proportion of five to one in its size, by which it appears that the veins of the spleen exceed the size of its arteries in a greater degree than is observed in the other organs of the body. Much, however, remains to be done in order to explain the anatomy of the spleen. To us the cells have appeared of different sizes, and to have a very free communication with each other, by which the organ, particularly towards the surface, resembles a good deal the texture of a sponge. We are doubtful whether the cells have coats proper to themselves, or whether they are not formed by the interspaces of the parenchymatous substance. The blood-vessels appear to communicate with the cells only by their ultimate and most minute ramifications. Cuvier states that the texture of the spleen is very loose in the *ornithorhynchus*, and that its vessels are much developed.

Fig. 5. Plate IV. of the Anatomy of Mammalia, gives a view of some of the spleens of the *porpoise* upon the first stomach, as pointed out by the letters *i, i, i, i*.

Peritoneum and its Processes.—This membrane has the same structure in mammalia as in man; but the reflexions of it, which form the omentum, and the envelopes of the in-

testinal canal, differ considerably in their figure and extent in some quadrupeds. The form and extent of the mesentery, mesocolon, and mesorectum, depend upon the length and convolutions of the small and great intestines, and may be in some measure calculated from the previous description of the intestinal canal. The uses of these parts are precisely the same as in man.

The great omentum varies in length in different mammalia, but in most of them it is longer than in the human subject. In some species it not only covers the front of the intestines, but extends into the pelvis, and is reflected forwards the length of the rectum. This reflection of the omentum is attached to the bladder, rectum, mesorectum, and to the sides of the peritoneum. The omentum is thus extended in many species of *monkey*, but the length of this membrane does not correspond with the agreement of the animals in general structure. Species nearly allied have it very different; for instance, in the *brown bear*, it does not pass below the middle of the abdomen, and in the *raccoon* and *badger* it reaches to the pubis.

The layers of the omentum have not always the same origin and connections as in man, which arise from the want or the presence of the transverse mesocolon. There is no omentum to the colon, or appendices epiploicæ in the carnivorous mammalia.

The *ruminating quadrupeds* have the cavity of the principal omentum very large. It incloses the four stomachs, the duodenum, and the pancreas.

The fat, which is deposited between the layers of the omenta, is found in all mammalia, but in greater quantity in the *herbivorous* than in the *carnivorous* tribes.

Some of the *hibernating quadrupeds*; for instance, the *Alpine* and *Polish marmots*, the *fuscic* (*mus citellus*), the *fat squirrel* (*myoxus glis* of Gmelin), and the *jerboa*, have lateral omenta in addition to those of other mammalia. These arise from the loins, cover the sides of the abdomen, sometimes even coming as far as the middle of the belly. About the period of hibernation, these processes of the peritoneum become, as well as the other omenta, loaded with fat, which is expended during the time that the animals remain torpid. The use of the lateral omenta is, therefore, sufficiently obvious, and yet it is very extraordinary, that they should be wanting in other species that sleep during the winter, some of whom also are nearly allied to those above mentioned; as, for instance, the *garden squirrel* (*myoxus nitela*), the *common dormouse* (*myoxus muscardinus*), &c.

Absorbent System.—This part of the anatomy of mammalia so much resembles what has been discovered in the human subject, that there has been no inducement to investigate it minutely; we, therefore, possess no detailed account of the absorbent system of this class of animals.

The chief varieties which have been observed, relate to the number and situation of the absorbent glands, and the form of the thoracic duct.

The *glands* are less numerous, generally speaking, in quadrupeds than man: they are also commonly larger. The *mesenteric glands* are perhaps in most quadrupeds assembled together into one or more masses; besides these masses, there are often some distinct glands in the mesentery. It is at the root of the mesentery that the glands are congregated into the chief mass. They are connected with each other by means of cellular substance, and present an unequal surface externally. The assemblage of the mesenteric glands was mistaken for a pancreas by Afellius, and have ever since retained the name of *pancreas Afellii*. In the *bear*, the *mole*, the *brown phalanger*, &c. there is only one mass. The *cat* kind, and perhaps all the *digitigrade quadrupeds*, have one principal

mass or cluster at the root of the mesentery, and near this some smaller ones. Cuvier states them to be the same in the *dolphin*. The pancreas Afellii is very large, and of an elongated figure in the *seal*. There are two masses of the mesenteric glands in the *weasel*.

In the *flying lemur*, the *common rat*, and the *cloven-footed quadrupeds*, the glands are dispersed over the mesentery. We have found them so likewise in the *grampus*. It is probably the same in the other *cetacea*. The cellular structure of the absorbent glands is very apparent in the *horse*, *ass*, &c.

A very singular structure has been described in the mesenteric glands of the *whale* by Mr. Abernethy. He represented them as forming round bags, about the size of an orange: these sacs contained a slimy fluid, which was apparently a secretion of their own. The lacteals not only terminated in these bags, but formed a plexus upon their surface. The blood-vessels likewise ramified upon the coats, and communicated with the cavity of the bags, so that a waxen injection passed into it. We feel inclined to consider the cysts described by Mr. Abernethy on the mesentery of the *whale* as a morbid structure, as we have found nothing of the same kind in those *cetacea* we have dissected, and as it has not been observed by Hunter, Cuvier, Blumenbach, or any other comparative anatomist, as far as we know.

The *thoracic duct* has generally in mammalia a considerable dilatation of its origin, or a large *receptaculum chyli*. The bulk and course of the thoracic duct are liable to vary amongst individuals of the same species, more particularly in domestic quadrupeds. Sometimes there is an annular dilatation at the upper part of the thoracic duct in the *dog*, which has been represented by Vans Bils as a constant structure, which he called the *receptaculum tortuosum*. The thoracic duct is double in some quadrupeds. It is so in the *dog*. Cuvier describes the duct in the *dolphin* as being complicated, and at last terminating in two branches, which open beside each other into the jugular vein. Mr. Home found in the *sea otter* the receptaculum chyli large, and the thoracic duct composed of two tortuous branches, which make many convolutions and communications with each other, and terminate separately.

Mr. Bracy Clarke has stated, that he found the thoracic duct of the *horse* forming several lateral communications at the lower part with the lumbar veins. (See *ANATOMY, Veterinary*, in this dictionary.) We cannot, however, help doubting the accuracy of the observation, as this fact would form so extraordinary an exception to the system of absorption, as it has been proved to exist in all the higher classes of animals.

Doubtless there are many varieties in the form of the thoracic duct, and the distribution of the absorbent vessels in mammalia, which have not yet been observed: but as they probably would not throw any light upon the function of absorption, they are but of little importance.

Heart.—This organ in mammalia corresponds in all material circumstances with the heart of the human subject. It is in every instance enclosed in a *pericardium*, notwithstanding Blaius, Peyer, Harder, Tozzetti, &c. have reported that this membrane is wanting in the *hedge-hog*. Blumenbach accounts for these anatomists having made such a mistake from the thinness of the pericardium in the *hedge-hog*; but to us this membrane has appeared not to be unusually thin, considering the size of the animal.

The position of the heart in the body is rather different from that of man. It is situated more in the direction of the animal's body, and rests rather upon the sternum than the diaphragm. We ought to except from this observation the

MAMMALIA.

the heart of the *ourang-outang*, which is placed obliquely in the breast, with the point turned towards the left side, as in man. It must have been from the dissection of quadrupeds, that the cavities of the heart first received the names of *right* and *left*, which are not strictly applicable to their situation in the human subject.

There are some differences in the relative size of the cavities of the heart, and in the thickness of the parietes of the right and left ventricles in mammalia, which are pointed out by Cuvier. He has also described some varieties in the form of the valves. As these are unimportant, we shall refer the reader to Cuvier's "Anatomie comparée," tom. iv. for the details. It is necessary to state that the valve of Eustachius is not found to exist in certain species; as the *lion*, the *bear*, and the *porcupine*. It is strong and muscular in the *seal*. In the *elephant* this valve is spiral, and is continued for the length of the superior parietes of the sinus, with the left and posterior extremity of another broad semilunar valve, that separates the orifice of the right and anterior vena cava from the cavity of the appendix of the auricle.

There are two superior, or more properly speaking anterior, venæ cavæ in the *elephant*; one left, the other right. The first opens into the sinus of the auricle, near the mouth of the ventricle. The same is observed in the *porcupine*. The *kangaroo* has also two superior or anterior cavæ. Mr. Carville states, that the *hibernating quadrupeds* have the superior cava divided into two trunks; the left passes over the left auricle of the heart, and opens into the inferior part of the auricle near to the orifice of the inferior vena cava. In some of the *ruminating quadrupeds*, and in the *pig*, there are two small flat bones at the origin of the aorta from the heart. It has been supposed that they supported the aortic valves. See C. J. Keuchen de Officulis et Cordibus Animalium.

A very common error, with respect to the anatomy of the heart, is the supposition that the quadrupeds which inhabit the water, and the *cetacea*, have the foramen ovale so much unclosed, that the two auricles communicate. The opinion has received some support from this communication being actually found to exist in a very few instances. Blumenbach relates that he was presented with the heart of a *seal*, in which not only the foramen ovale, but the ductus arteriosus remained unclosed. Seger found the ductus arteriosus open also in the same animal. (Ephem. Nat. Curios. dec. 1. an. 9.) The foramen ovale has been seen in an open state twice by Mr. Home, in the *sea otter*. In the other numerous dissections which have been made by the most expert anatomists of the *diving quadrupeds* and the *cetacea*, the heart has been observed to possess the four cavities separate, as in man and the other mammalia. Our own experience is amply sufficient to enable us to conclude that any communication between the cavities of the heart in these animals is not a natural or necessary structure. That it may occasionally exist is not improbable, and that these animals may be particularly liable, from their habits, to such malformations of the heart, seems also not unlikely; but it would be absurd to found an opinion upon the exceptions to what is so well known to be the general rule. We might further add, that the foramen ovale is frequently found more or less unclosed in the human subject, without having occasioned any embarrassment or peculiarity in the pulmonary circulation during the life of the person. We have observed, that it is even more commonly imperfectly closed than otherwise in the human subject. In most dead bodies that we have examined, we could at least pass a probe obliquely from the right into the left auricle.

The *otter* has been reported to have three communications

between the auricles; but these were nothing more than the foramina Thibessii, perhaps in an enlarged state.

The external form of the heart is in some species elongated, in others broad. The point is blunter or rounder in some than others, but these varieties do not merit a particular notice. In the *lamantin* the figure of this organ is, however, very peculiar. It is much broader than it is long. The ventricles are actually separated half way from their end, so that there are two points or apices to the heart.

Arteries.—The structure of these vessels is perfectly similar in man and mammalia. They consist of the same number of coats, and in general have a similar relation in their diameter and the thickness of their parietes. The quadrupeds that inhabit rivers or the sea, and the *cetacea*, are distinguished by a large size of their blood-vessels, in proportion to that of the entire bulk, or the size of the other organs of the body. In some *cetacea* the principal trunks have a diameter nearly equal to that of the intestinal canal. The branches of the blood-vessels also in these animals are very large in proportion to the trunks from which they arise. The circulation appears to be much less free in aquatic animals than others, and hence the great size of the vessels and the accumulation of blood in *fishes*, which circumstances are also to be observed in a less degree amongst those mammiferous animals that live in the water. It seems to us, that the arteries of the *cetaceous* mammalia have thinner coats than in other animals of the same class, according to the size of the vessels. The *pulmonary* artery in the *cetacea*, however, has nearly as strong coats as the aorta.

The chief varieties to be noticed in the arteries of mammalia are the different origins of the trunks; the greater size of particular vessels; and the plexuses that are formed in certain species.

The *aorta* in the *ruminating quadrupeds*, the *horse*, the *rhinoceros*, the *hog*, the *pecari*, and probably in other instances not yet discovered, divides almost immediately upon its origin into two large trunks. One of these, which is the smaller, proceeds upwards, or more properly forward, in the body of a quadruped; and it corresponds to the arch of the aorta, and furnishes the same branches. The other trunk goes backwards, and takes the place of the descending aorta.

The first branches of the aorta have different origins in mammalia. In the *marmot* and *guinea-pig*, the arch furnishes only two primary branches. One of these sends off the two carotids, and then ends in the right subclavian. The other is the left subclavian artery. Sometimes the first of these branches very soon separates into two others, one of which is the left carotid, and the other produces the right carotid and subclavian. In other cases, the first of the primary arteries of the aorta furnishes a branch which divides into the two carotids. The remainder of the artery is the right subclavian. This last mentioned distribution exists in the *lion*, *dog*, *cat*, and *bear*.

In the *dolphin*, each of the two primary branches of the arch of the aorta furnishes the arteries of the head, and superior extremity, on its proper side.

The *seal* has three principal branches from the arch of the aorta: the first is the common trunk of the right carotid and subclavian, the second the left carotid, and the left subclavian.

The *elephant* has three branches from the arch of the aorta also. The lateral vessels are the two subclavian arteries. The middle one divides into the two carotids.

The *goat* has the aorta divided, as already described, into the ascending and descending, or the anterior and posterior, more properly called. The anterior divides into three branches:

MAMMALIA.

branches: the left subclavian; the right; and a trunk that forms the two carotids.

The anterior aorta of the *horse* soon bifurcates into two branches; the trunk of the two carotids and the right subclavian arise from one branch: the other terminates in the left subclavian.

The *inferior thyroidal* artery is not commonly in quadrupeds a branch of the subclavian, but of the carotid higher up. This distribution arises from the length of the neck removing the thyroid gland so far from the usual origin of this vessel.

In the *opossums*, the *kangaroo*, and as it would appear in all the *marsupial* quadrupeds, the *brachial* artery divides very high up into the ulnar and radial arteries; in some instances as high as the middle of the humerus. The ulnar is a large vessel, and passes through a hole formed in the internal condyle of the os humeri, and proceeds from the back of the arm to the front, where it is distributed in the usual manner. Cuvier states that the brachial artery forms several branches for the supply of the portion of the fin corresponding to the fore arm in the *dolphin*. The very remarkable plexus which the brachial artery furnishes in the *tardigrade quadrupeds*, will be noticed hereafter, along with the other arterial plexuses.

Daubenton has described in the *descending* or *posterior aorta* of the *pecari* a large dilatation, which appears to have been an aneurism. Tyson found in the same animal three dilatations in the course of this vessel. They were divided interiorly into cells. These enlargements were probably also a morbid structure, as they have not since been observed by other anatomists.

There are some varieties to be noticed in the branches of the *cœliac* and *mesenteric* arteries. In the *cat* the *cœliac* sends off a branch to the right renal capsule, previous to its supplying the *hepatic*, the *coronary* of the *stomach*, and the *splenic*. In the *porcupine* the *cœliac* divides into two branches; one furnishes the artery of the spleen, and a large branch to the pancreas; the other gives the hepatic and coronaria.

The two *mesenterics* always are found; but when there is no marked distinction of great and small intestines, the one corresponding to the inferior mesenteric is very small. This vessel is almost exclusively distributed to the rectum in the *bear*. In the *ruminating quadrupeds* the primary branches of the superior mesenteric artery are numerous. They do not consequently form such frequent anastomoses as exist commonly. The *inferior*, or, as it should be called in quadrupeds, the *posterior mesenteric* artery, is small in these animals, and almost confined to the rectum. The remarkable anastomosis between the two mesenterics on the colon is not found.

In the *seal*, the left kidney receives two arteries from the aorta, and the right only one, according to Cuvier. This not improbably may have been a variety.

The *middle artery* of the *sacrum*, which is so inconsiderable in man, is often very large in mammalia, as it conveys almost the whole of the blood to the tail. In the *kangaroo*, *bear*, *lion*, *dog*, &c. it has been observed not to arise from the aorta, but to be furnished by a thick short trunk proceeding from the bifurcation of the aorta, which also in these cases sends off the *sacra laterales* and the *hypogastric* arteries. The artery of the tail is as large in the *kangaroo* as the internal iliac. This vessel is of great magnitude also in the *cetacea*. It runs along the under surface of the tail, protected by a number of small bones, which are attached to the caudal vertebræ, to near the extremity of the tail, and form by their opposition a sort of triangular conduit, similar to that inclosing the termination of the aorta in the tail of fishes.

The artery of the tail might properly be considered the continuation of the abdominal aorta in the *cetacea*; it sends off a great many branches which anastomose with each other, and unite again in a small branch under the two last caudal vertebræ.

The *primary iliac arteries* frequently do not exist in the *cloven-footed quadrupeds*, the *cat* and *dog* kind, the *bears*, the *kangaroo*, &c. The *external iliacs* are formed by the bifurcation of the aorta, and the *internal iliacs* arise from a common trunk, as already mentioned. They are much smaller than the external iliacs, and separate into two principal branches, which send off the customary arteries of the internal iliac, except the *ileo lumbalis*, which comes in these instances from the external iliacs.

In the *seal* the *ileo-lumbales* arise from the aorta before the primary iliacs are produced.

In the *cetacea* there are no arteries analogous to the external iliacs. The aorta sends off arteries which correspond to the internal iliacs, but which only supply the bladder and genital organs.

We shall now notice the different plexuses which the arteries form in mammalia.

In the *digitigrade quadrupeds*, some of the *ruminants*, &c. the branches of the carotid, which go to meet the basillary, form so remarkable a plexus, that it was called by the older anatomists *rete mirabile*. These branches of the carotid are suddenly dissolved into an immense number of small vessels, which are twisted and united together like a plexus of nerves. These plexuses fill up the sides of the sella turcica, and afterwards reproduce the two branches that, uniting with the basillary artery, establish what is called the circle of Willis. It is not known in how many species the *rete mirabile* exists; it was formerly supposed to be universal in mammalia. The Parisian dissectors did not find it in the *monkey*, and Cuvier says it does not exist in the *elephant* and *beaver*.

Mr. Carlile has mentioned a similar plexus of the carotid artery near the jaws in the *lion-ox*, and *sheep*.

We have observed in the *grampus* a very intricate plexus of vessels around the articulation of the lower jaw. We did not ascertain whether the vessels were arterial or venous: they appeared to be both, and were lost in the appearance of ligamentous cells.

The *intercostal arteries* in *cetacea* form a very remarkable plexus. It appears to be made by the convolution of one vessel, which measures several hundred feet in length.

The arteries of the spinal marrow also in *cetacea*, are converted into a close plexus throughout the greater part of the spinal canal. In the *grampus*, the section of the sheath of the spinal marrow exhibits a number of the orifices of these vessels all round it.

But the most interesting arterial plexuses, are those described by Mr. Carlile in the limbs of the *slow-moving animals*. In all these, as well as the *tardigrade lemurs*, as the *stots*, the axillary and iliac arteries produce a plexus of undulating branches, which vary in number according to the species. Mr. Carlile describes the trunks of the arteries as being expended in the formation of the plexuses; but we have ascertained that the trunk of the vessel is continued beneath the plexus, in the same manner as in the plexus of the anterior tibial artery in birds where the trunk is scarcely diminished. The vessels composing the plexus in the anterior extremity of the *lemur tardigradus* amount to 23. In the inguinal fasciculus there are 17. These vessels have the same size throughout their course, and occasionally anastomose with each other.

The brachial and inguinal plexuses are larger in the *great American sloth* than in the *tardigrade lemur*. In the first Mr. Carlile counted 42 vessels, and computed from the bulk that there

there might have been above 20 more concealed in the middle of the *falciculus*. He reckoned only 34 in the thigh, and those of the first series were larger than the rest. The plexus of the axillary artery in the *two-toed sloth* is very inconsiderable, and disappears in the upper part of the humerus, although in the other instances it reaches to the elbow. The inguinal plexus also in this animal contains but eight vessels, which soon begin to ramify in the usual arborescent form.

In the *lori* (*lemur gracilis*) there are brachial and inguinal plexuses, the vessels of which appear to form fewer anastomoses than in the other animals. From the agreement in the distribution of the arteries in the limbs of the *slow-moving* animals, it is impossible not to admit Mr. Carlile's supposition, that this peculiar arrangement of vessels is necessarily connected with the slow operation of the muscles in those quadrupeds, although we cannot perceive why such a connection should exist.

The *rete mirabile* has evidently the effect of retarding the current of the blood to the brain, which may be more necessary to quadrupeds, from the frequent low position of the head, than in *man* and the *monkey*, where this plexus does not exist.

It is difficult to account for the intercostal, spinal, and maxillary plexuses of the *cetacea*, unless we suppose that they serve as reservoirs of the blood, or rather prevent an accumulation of blood in larger vessels, which might arise from their continual residence in the water, and frequent suspension of their respiration.

In Plate VI. of the *Anatomy of Mammalia*, *fig. 4.* represents the *rete mirabile* of the carotids in the *cat*, somewhat above the natural size: *a*, the *fella turcica*, a little pared away, to shew more plainly the plexus, *b*, on each side; *c, c*, are the carotid arteries; *d*, the basilar. *Fig. 5.* of the same plate, is to shew the axillary plexuses of the *tardigrade lemur*: *a* is the trunk of the axillary artery; *b*, the plexus; *c, c*, the arteries of the fore-arm resuming their proper form. *Fig. 6.* exhibits the plexus of the iliac artery in the same animal: *a*, the trunk; *b*, the plexus; *c, c*, distinct vessels for supplying the leg. *Fig. 7.* shews the axillary plexus in the *three-toed sloth*: *a* is the sub-clavian vein; *b*, the trunk of the artery behind the large veins; *c*, the remarkable plexus which the artery forms; *d*, the median nerve. *Fig. 8.* represents the brim of the pelvis and groin of the *three-toed sloth*, with the plexus of the inguinal artery: *a* is the bifurcation of the aorta into the two iliacs; *b*, a part of the internal iliac muscle; *c*, part of the bony margin of the pelvis, leading down to the pubis.

Veins.—These vessels agree in general exactly in mammalia with those of the human subject. Even where the arteries deviate in their origin from what is observed in man, the veins pursue the ordinary course.

We have already mentioned that there are two superior or anterior *cavæ* in the *porcupine*, *elephant*, the *kangaroo*, and the *hibernating mammalia*. Mr. Carlile has stated, that, in addition to the *cavæ* forming two trunks before approaching the heart in the quadrupeds that remain torpid during the winter, there are also two trunks to the *vena azygos*, which each open into the superior cava, on its own side of the thorax. He likewise remarks, that the intercostal arteries and veins are particularly large in those animals. Mr. Carlile wishes to infer from this distribution of the venous trunks, that it is necessary, on account of the languid circulation that is carried on when the animal is torpid; but we believe it is vain to attempt the explanation of the phenomena of hibernation by the anatomical structure of the animals concerned. The habit of retiring to rest during the winter is common to animals whose anatomy is extremely different, and if the dimi-

nished action of torpid animals were to depend upon any particular organization of their vascular system, it would interfere with their perfect circulation at other seasons. Hibernation is accompanied by a suspension of functions, not a different mode of exercising them.

In the *seal* the inferior vena cava is dilated into a large sinus, as it passes the liver, into which five large hepatic veins enter. This dilatation may be either the consequence of the animal living in an element in which its respiration, and consequently free circulation is so often interrupted, or it may be an original provision of nature, to relieve the right side of the heart, when the current of blood through the lungs is impeded during the moments the animal is under the water.

A similar contrivance seems to exist in the *horse*. There is a dilatation of the *jugular vein* behind the jaws in this animal, which may serve to relieve the brain from the pressure of the venous blood during the time this animal is feeding. The ruminating quadrupeds do not require a provision of this kind so much as the *horse*, as they often eat lying, and generally ruminate so.

The veins of the viscera appear to be provided with valves in some mammalia, like those of the members in man. According to Haller, there are valves found at the origin of the branches of the *mesenteric* and *hemorrhoidal* veins of the *horse*; and they have been observed also in the *splenic* veins. They exist in the *pulmonary* veins of the *dog* and *sheep*. Most probably they may be found in many other instances, where they have not yet been observed.

The texture of the coats of the veins is apparently the same in man and in mammalia. Cuvier says he found the proper membrane to tear, like felt, into long silky filaments, in the axillary vein of the *elephant*, which he considers an example of the structure of this coat generally.

Vital Temperature.—That degree of heat which an animal sustains most commonly, or when not exposed to extremes of external temperature, we have called the *natural standard*. The standard heat of *mammalia* is several degrees higher than in *man*, although still below what is found to be the natural temperature of *birds*.

The thermometer, when introduced into the rectum or urethra of a man, (for the standard can only be ascertained in the cavities,) rises to 97°.

The following experiments were made by Mr. Hunter, and shew the difference in quadrupeds.

The ball of the thermometer [in every case we are to be understood as speaking of Fahrenheit's scale] being introduced two inches within the rectum of a healthy *dog*, the quicksilver rose to 100½° exactly. The chest of the *dog* was opened, and a wound made into the right ventricle of the heart. Immediately on the bulb being introduced, the quicksilver rose to 101°.

A wound was next made into the substance of the liver, and the instrument being inserted into it, rose to 100¾°. It was next introduced into the cavity of the stomach, where it stood exactly at 101°.

The thermometer was introduced into the rectum of an *ox*, and the quicksilver rose to 99½°.

When inserted into the rectum of a *rabbit* it stood also at 99½°.

Doctör Martine, in his *Essays upon Thermometers and Heat*, states that the temperature of the surface of the body is from 100° to 102°, or sometimes 103°, or a little more, in ordinary quadrupeds, as *dogs*, *cats*, *sheep*, *oxen*, *swine*, &c. in which he is certainly incorrect. We have been led to ascertain the usual temperature of several quadrupeds, previous to making different experiments that would be irrele-

MAMMALIA.

vant to our present purpose, if related here; but we may state that we have always found the heat of the cavities of the body to be about 99° , 100° , or 101° , when the quadrupeds were placed in a medium natural to them, and that of the surface of the body, two, three, or more degrees, according to circumstances, below that of the interior of the body. In quadrupeds, generally, we conceive the *standard* temperature should be stated to be 100° .

The heat in *cetacea* we should suppose to be equal to that of quadrupeds, or perhaps higher. The quantity of oil interposed between their internal parts and the water would seem to be sufficient to prevent the abstraction of heat, and that circumstance, joined with the want of evaporation from the surface, might even tend to exalt the temperature of the interior part of the body. Boerhaave considered the heat of *cetacea* to be the same as in quadrupeds, but he rates it in both too low. Mr. Richer found the blood of the *porpoise* to be as warm as the blood of land animals. Du Ham. Hist. Ac. Sc. P. M. 157, and Mem. de l'Acad. des Sc. 1666—1668. Dr. Martine relates that he found upon trial the heat of the skin of the *sea-calf* (*phoca vitulina*), to be near 102° , and in the cavity of the abdomen it was about a division higher.

We may safely conclude from the facts before us, that the standard temperature in all mammalia surpasses the human by a few degrees. In what manner can this fact be explained? should it be attributed to there being less evaporation from the skin; or the natural integuments of mammalia being better calculated for retaining the vital heat? We do not pretend to answer these queries, but we shall observe that although the natural clothing of an animal evidently tends to preserve its temperature from the influence of external cold, it does not seem capable of giving a higher standard. We cannot believe that the standard of a *bear* could be altered by depriving the creature of its fur.

Mammalia have, both from their usual coverings, and the high natural standard, great powers of resisting the effects of external cold. Many of them are exposed to great extremes of temperature in the northern climates, in which they suffer more than birds, from sleeping on the ground. Mr. Hunter failed to freeze a *dormouse*, when surrounded by a freezing mixture, until he wetted its hair with water. And in another experiment, a *mouse* which he had placed in an atmosphere as low as 13° above 0 during an hour, had not its heat diminished more than 16° at the diaphragm, and only 18° in the pelvis.

Like all other animals, however, which possess a high standard, when this is brought very low in mammalia they perish. When in a torpid state they suffer a great reduction of their natural temperature, with the same impunity as the more imperfect animals. Thus, in an atmosphere of 26° , a torpid *hedge-hog* was only 30° , although the same animal, when roused, was exposed for two days to the same atmosphere, and the internal heat, as tried by the rectum, did not sink below 93° .

Lungs.—These organs have their general figure regulated, in some degree, by the shape of the thoracic cavity. In those species which have the chest short it is commonly wide in proportion, and the convexity of the diaphragm is not considerable; and, on the contrary, where the thorax is long, it is often narrowed and diminished in the longitudinal direction, by the diaphragm being very convex, or projecting far into the chest. In the *rhinoceros*, *horse*, *elephant*, and *two-toed sloth*, the diaphragm passes up into the thorax, far beyond the margin of the ribs, so that it receives a part of the abdominal viscera. The volume of the lungs is, therefore, still preserved in due proportion to the size of the

animal, notwithstanding the external form of the chest might sometimes make it seem otherwise.

The lungs of mammalia are commonly divided into a greater number of lobes than those of the human subject, although there are some species which have them less so, or even not separated into lobes at all. The number of the lobes of the lungs is not conformable to any natural classification of mammalia, but varies even amongst individuals of the same species.

Cuvier has given in his "Anatomie comparée," tom. iv. a very full table of the divisions of the lungs of mammalia by lobes and fissures, from which we shall select the following account.

In the *ourang-outang*, there are three lobes in the right lung and two in the left, as in man.

The *long-armed ape* has four in the right, and only a fissure in the left. The rest of the *monkey* genus have commonly four lobes in the right, and two in the left lung: in some of these there are fissures.

The *lemurs* have four or three lobes to the right, and two or three in the left lung.

The *flying lemur* and the *common bat* have the lungs undivided, except by fissures. The *great* or *ternate bat* of Edwards, has four lobes in the right, and three in the left lung.

The *plantigrade* mammalia have generally four in the right, and two or three in the left. The *common hedge-hog* has, however, four in the right lung, and no division of the left.

In the *digitigrada* there are four lobes in the right, and three or two in the left.

The *marsupial* quadrupeds (except the *kangaroo-rat*) have the left lung undivided, or slightly so, by one fissure. The *phascolomys* has no lobes, but two fissures in the right lung. The *kangaroo-rat* has four lobes in the right lung, and two in the left. The *Virginian opossum* has three in the right lung: the other species of *didelphis* have either three lobes, or two and a fissure to the right lung.

The *saltigrade* quadrupeds have most commonly the right lung divided into four lobes, and the left is frequently entire. When the left lung is divided, it is usually into two lobes; but in the *Hudson's Bay rat* there are four lobes, and in the *jerboa* three. The *porcupine* has six lobes to the right lung, and five to the left.

In the *edentata* there are two, three, or four lobes to the right lung, and either two or none in the left.

In the *elephant* and *rhinoceros*, both the right and left lungs are without lobes. The *daman* has two fissures to each lung. The *wild boar* has three lobes in the right lung, and two in the left. The *Siamese hog* has four in the right, and two in the left lung.

The *ruminating* quadrupeds have generally four lobes in the right lung, and two in the left. The *lama*, however, has the left lung only divided by a fissure.

In the *solipeda* there are no lobes to the lungs of either side.

The *seal* has two lobes in the right lung, but none in the left. The *lamantin* is without lobes.

The *cetacea* have not their lungs divided into lobes. Some of the *mammalia* are said to have the lungs adhering to the parietes of the chest. The *elephant* is reported to be an instance of this kind, and Tyfon has also stated it to be the case in the *web-footed* and *cetaceous* mammalia. In those species we have examined the lungs have been free, as in the human subject. In the *cetacea* the coats are strong, and the lung altogether feels firm and fleshy. Hunter states, that the lungs of *cetacea* possess so much elasticity,

MAMMALIA.

city, that they are of themselves sufficient to express the air from their cells. He also represents the air-cells as being smaller than they are in quadrupeds.

The intimate organization, which consists in the distribution of the arteries, veins, and the air-tubes, is perfectly the same in all mammalia and in man.

Bronchial Gland.—The use of this part not being established by anatomists, it cannot have a proper place assigned to it according to any physiological arrangement. We shall, therefore, describe it next to the lungs, from its contiguity to these organs in the body, without endeavouring to show any connection between the functions of the bronchial gland and respiration.

The size of the bronchial gland is greater in the human subject than in any other animal. In proportion to the entire bulk, there is very little difference observed in mammalia, except in the *kangaroo*, which has a particularly small bronchial gland.

This gland is composed of two lobes, as in man; but they are sometimes quite unconnected with each other, as in the *bat*, in some species of *rat*, the *elephant*, the *daman*, the *solipeda*, and the *seal*. Most commonly the two lobes are conjoined by one or sometimes two thin stripes, which pass over the front of the trachea.

The form of the lobes varies in different species. They are broader above than below in the *bat*, elongated in the *plantigrada*, long and flattened in the *cat* kind generally, still longer and cylindrical in the genus *viverra*. In the *saltigrada* the lobes are elongated, and not quite cylindrical, being thicker above than below. The figure of the gland varies in the *ruminants*. It is round and tolerably large in the *lama*, longer in the *ox*, *sheep*, and *antelope*.

In the *solipeda* the gland is but little elongated, and situated far below the larynx.

Hunter denied the existence of the thyroid gland in the *cetacea*, but Cuvier asserts that he found it very distinctly in many *porpoises* and *dolphins*, consisting of two parts suspended to the trachea, opposite to the superior, or rather anterior edge of the sternum. We have not perceived it in the *porpoise* or *grampus*, perhaps, from not seeking it far enough from the larynx.

In *man* and the *monkey* the cellular substance connects the thyroid gland closely to the sides of the trachea, but in the other mammalia this connection is looser. It is so much so in the *rabbit*, *guinea-pig*, and some other of the *saltigrade* quadrupeds, that the thyroid gland is moveable.

The internal structure of the thyroid gland appears to be the same in man and mammalia. The observations that have been made upon it in the *elephant* have tended to explain its organization, as from the size of the animal the gland is large. It is surrounded by a thick aponeurosis, in the substance of which the thyroid vessels divide before they penetrate the gland. Each lobe of the gland is composed of about thirty lobules having a firm texture, and separated by peculiar cells, which are made by an extremely fine membrane. These cells are but slightly connected with each other, and with the lobules which surround them, so that they appear to serve only as the foundation for the smallest ramifications of the vessels that enter the gland. It is by means of these vessels, rather than the cellular tissue, that the different lobules are joined together.

According to Steller, the *northern lamantin* has the thyroid gland very large; it contains two fluids, differing from each other in colour and consistence. The external part of the gland is composed of a number of very small grains, and of a fluid resembling milk in colour and consistence, and hav-

ing a sweet taste. There is a membranous sac in the middle of the gland, containing a thick and rather bitter fluid. It seems to be secreted by the grains, and deposited in the sac.

The existence of cells so plainly proved in the thyroid gland of these large animals, seems to justify the opinion entertained by some anatomists, that the cellular structure observed in bronchocele is produced by the natural cells of the part becoming enlarged.

It is a remarkable circumstance, which may throw some light upon the functions of the thyroid gland, that it only exists in man and mammalia. Cuvier seems inclined to consider a round cellular gland placed before the heart in the *serpents* as analogous to the thyroid of mammalia. It does not seem probable, however, that an organ should be wanting in *birds*, and re-appear in certain animals of a class one step farther removed from mammalia.

Kidnies and Urinary Bladder.—The position of the kidneys in the abdomen is different in man and mammalia, inasmuch as the latter commonly have the right kidney higher than the left.

The kidneys of mammalia usually possess the figure of the human. In the *cat* kind, the *coati*, the *armadillo*, the *gazelle*, &c. they are more or less round. In the *ruminating* quadrupeds, the *paca*, the *hog*, and the *porcupine*, &c. according to Cuvier, they are long-shaped. The *lama* has them nearly cylindrical. They are short and triangular in the *horse*.

In *man* and some *mammalia* the kidneys before birth are in separate lobules. In those mammalia that inhabit, or frequently visit, the water, and in a very few others, these glands preserve the distinctly lobulated appearance during life. The original lobules can, however, be always perceived, and reckoned from the number of their papillæ. They may be injected also with different coloured fluids, and not occasion any confusion, although they are consolidated into one mass.

The *elephant* is one of the animals which have lobulated kidneys. They are, however, not much divided, there being only four lobes to each in this animal. The texture of the *elephant's* kidneys is soft, and the distinction of the cortical and medullary substances is not plain. There are three papillæ, and as many infundibula, which join together without forming a pelvis.

The kidneys of the *ox* are still more divided than in the *elephant*, having from 23 to 30 lobes.

It is in the *otters*, *bears*, *seals*, and *cetacea*, that the lobulated structure is most distinct. The lobes are numerous and small in proportion, according to the succession of these animals. Thus, in the *otter* there are ten lobes to each kidney; in the *bear* there are from 50 to 60; the *seal* has 120 to 140; and in the *porpoise*, *dolphin*, *grampus*, &c. there are upwards of 200. In the *cetacea*, the lobules or glands of which the kidneys are composed, are particularly distinct and small in proportion to the size of the viscus. They are connected almost entirely to each other by means of their vessels alone, in the manner of a bunch of fruit, and have a good deal of motion upon one another. In the other animals they are more preserved in their proper situation, and in contact with each other by means of their cellular substance. No satisfactory physiological reason has been given for the kidneys being divided into numerous distinct glands in certain animals and not in all. It has been conjectured that this structure was in some way connected with the habit of diving, on account of its being met with in all the aquatic mammalia; but, as we have before stated, it is

MAMMALIA.

not peculiar to them. Like many other peculiarities of structure it must remain unexplained, until it be investigated by experiment.

The number of papillæ indicate both the original and the actual number of lobes that compose the kidney. There is but one papilla in the *tanrec* and the *ceati*; in the *squirrel*, the *hare*, the *guinea-pig*, the *daman*, and many other of the *lagigrada*. There are two in some *rats*, three in the *elephant*, four in the *echidna*, and five in the *hedge-hog*. In the *otters*, *bears*, *fin-footed* and *cetaceous* mammalia, each separate lobe has its proper papillæ.

The papillæ regulate in a certain degree the number of infundibula. When there is but one papilla the infundibulum is commonly absent, being confounded with the cavity called the pelvis of the kidney. This is particularly to be seen in the *cat*, the *dog*, the *armadillo*, &c. in which the medullary substance that forms the papillæ does not project into the cavity, but is flat or sometimes hollow: therefore, the cavity which receives the urine, and is the origin of the ureter, cannot send off any processes or funnel-shaped reflections of its membrane. The pelvis of the kidney in these cases is not visible on the outside.

The lobulated kidneys have a calyx or infundibulum to each of the glands that compose them. They unite to form trunks of vessels, which make at last something like a pelvis for the ureter to arise from in the *bears*, *otters*, and *seals*. In the *cetacea* there is no pelvis; the ureter is formed by the junction of some branches from the anterior infundibula, and receive the branches of the other infundibula afterwards, without forming any dilatation corresponding to the pelvis.

The *renal arteries* and *veins* do not enter at one place always: this is occasionally seen in man. The *adipose arteries* also are of various sizes, but in the lobulated kidneys, the vessels penetrate the organ at the nearest place, instead of passing in preference at the sinus, or the part where the excretory ducts come forth.

The veins of the kidneys in the *cat* kind have their principal trunks and branches running in an arborescent form upon the surface. They receive the branches from the internal part of the gland, as the sinuses of the dura mater collect the blood from the brain.

The intimate structure of the kidneys in all mammalia appears to be the same as in the human subject.

The chemical composition of the urine appears not only to vary considerably in animals resembling each other, but even to differ in the same animal at different times. In this way one may account for the disagreement in the analysis published by the French and English chemists.

The urine in the *camel*, according to Mr. Brande's experiments, is composed as follows:

Water	-		75
Phosphat of lime		}	
Muriat of ammonia			
Sulphat of potash			6
Urat of potash			
Carbonat of potash			
Urea			6
Muriat of potash			8
			95

Rouelle states the *camel's* urine to be composed of carbonat of potash, sulphat of potash, muriat of potash, urea, and water.

Mr. Brande found the following component parts in the urine of the *cow*:

Water	-		65
Phosphat of lime			3
Muriat of potash		}	
ammonia			15
Sulphat of potash			6
Carbonat of potash		}	
ammonia			4
Urea			4
			97

But from Rouelle's examination, it consists of carbonat of potash, sulphat of potash, muriat of potash, urea, and benzoic acid. Both these chemists agree that potash is the only fixed alkali in the urine of the *cow*.

The urine of the *rabbit*, according to Vauquelin, is composed of the following parts: carbonat of lime, carbonat of magnesia, carbonat of potash, sulphat of potash, sulphat of lime; muriat of potash, urea, gelatine, and sulphur.

The same chemist found that the urine of the *guinea-pig* deposited carbonat of lime; that it changed the colour of syrup of violets to green; and that it contained carbonat and muriat of potash, but not any phosphat, nor the uric acid.

From these examinations it would appear that soda and its combinations do not form any part of the urine of the *camel*, *cow*, *guinea pig*, and *rabbit*.

In the urine of the *horse* the following component parts have been discovered by Fourcroy and Vauquelin:

Carbonat of lime	-		11
— soda			9
Benzoat of soda			24
Muriat of potash			9
Urea			7
Water and mucilage			940
			1000

Mr. Brande found the urine of the *horse* to contain the following salts, *viz.* carbonat of lime and of soda, sulphat of soda, muriat of soda, benzoat of soda, and phosphat of lime, which parts amounted to about $\frac{1}{4}$ th of the urine.

The urine of the *ass*, according to the same chemist, is mucilaginous, but at the same time transparent. Like that of the *horse*, it changes vegetable blues to green, but deposits no carbonat of lime. It differs in composition from that of the *horse*, by containing a much greater relative proportion of phosphat of lime and urea: it also contains carbonat, sulphat, and muriat of soda, and there appeared to be a small quantity of potash, which is probably united to muriatic acid. He did not discover any benzoic acid.

It deserves to be remarked, that the urine both in the *horse* and *ass* is destitute of ammonia.

The urine of quadrupeds appears to have generally more mucilaginous than in man. It feels particularly unctuous or mucilaginous in the *horse*, *ass*, and *cow*.

Fig. 1. Plate VII. of the *Anatomy of Mammalia*, exhibits the lobulated kidney of the *beaver*.

The *urinary bladder* exists in all mammalia, and resembles, in general very closely, that of the human subject. Its muscular coat is particularly strong in some quadrupeds: it is most strikingly so in the carnivorous species, and a few herbivorous quadrupeds. The fasciculi of the bladder are,

in these instances; very thick, and generally contract the bladder when the animals die; by which it is supposed to have a smaller cavity than it really possesses during life. In the large graminivorous quadrupeds the muscular coat is generally weak, and hence the great distention that the bladder admits in these animals by inflation.

The bladder of the *echidna* and the *ornithorhynchus* terminates in a long neck or tube, which opens by a small foramen into the cloaca, as in the *tortoise*. The ureters and vasa deferentia open close to each other into this tube, before the bladder. The urine, therefore, must return, or regurgitate into the bladder, in the same manner as in the *tortoise*.

This fact is displayed in *fig. 5. Plate VII. of the Anatomy of Mammalia*. The letter *g* indicates the tube; *i, i*, are the orifices of the ureters before the neck of the bladder; *b* is the opening of the tube into the cloaca; *k* is the urinary bladder.

Renal Capsules.—The French academicians have stated, that these parts are deficient in the *Canada stag*; but this appears to have been a mistake, as no instance of their being wanting in mammalia is mentioned by other writers.

The relative situation of the capsules to the kidneys is nearly the same as in man. Sometimes they adhere to the kidneys, but, almost constantly, the right is attached to the vena cava.

The magnitude of these bodies differs very much according to the species, besides the variations depending upon age, which seem to be less than in man; and in the *guinea-pig* the capsules are even larger in the adult than the foetus.

The relative bulk of the renal capsules to the kidneys is as great in the *monkey* as in *man*. Cuvier found it to be as 1 to 16 in the *varied ape* (*simia mona*), and as 1 to 12 in the *simia patas*. He found it to be $\frac{1}{3}$ d in a *young howling baboon*.

In the *digitigrada*, Cuvier found the renal glands to be $\frac{1}{3}$ th the size of the kidneys in the *tiger*, and in the *lynx* the $\frac{1}{4}$ th.

They are the $\frac{1}{6}$ th in the *hedge-hog*; the $\frac{1}{10}$ th in the *kangaroo*; but the other *saltigrada* in general have the renal capsules large. In the *guinea-pig* they are in the proportion to the kidneys of 1 to 5: they appear to be largest in some of the *rat* genus, in which they equal the $\frac{1}{4}$ th of the kidneys during the whole life of the animal.

The *opossum* has them only amounting to the $\frac{1}{5}$ th of the size of the kidneys.

In the *horse* they are the $\frac{1}{10}$ th.

Cuvier found the renal glands smaller in the *seal* than in any of the whole class. This animal has them only the $\frac{1}{15}$ th part of the size of the kidneys.

The form of the renal capsules is very various, but corresponds, in some degree, with that of the kidneys; thus, when the latter are lobulated, the capsules are commonly so also.

In the *ruminating* and *solid-footed* quadrupeds, these parts resemble the renal capsules of the human subject, being flat and triangular.

In the *elephant* they are long, conic, and have their base turned backwards, and divided into two round lobes.

In the *paca* and the *porcupine*, they are elongated and cylindrical. In these, and a great many mammalia, they resemble very exactly the kidneys. In the *coati* and the *daman*, they have a sinus like the kidneys.

In the *seal* and the *cetacea*, they are flat and triangular, but divided into many lobes, which coalesce in the centre. The lobules are more separate in the *cetacea* than in the *seal*.

The structure of the renal capsules is the most interest-

ing part of their history, but it is involved in some obscurity. The vein which collects the blood of the capsule commonly forms a dilatation in the centre, which seems to have been sometimes mistaken for a peculiar cavity. Cuvier, however, has described three little pouches in the renal gland of the *elephant*, which he found to be covered with a very delicate, smooth, white membrane, that exhibited no orifice of any blood-vessels. This membrane appeared to be moistened with a clear mucous fluid. The bottom of one of the pouches had a little hole, which communicated with a fourth pouch, occupying the internal and posterior lobe of the capsule.

The appearance of two substances composing these glands is generally the same in mammalia as in man. The external or yellow portion of the capsule appears to correspond with the cortical substance of the kidneys. It is of a brighter colour generally in animals than man, and is often so thick as to occupy more than the half of the gland. Cuvier says, that it is composed of fibres or tubes situated in a perpendicular direction with respect to the internal substance. This last is soft, and of a deep brown colour.

In the *coati* three substances have been observed: one grey, which forms the nucleus. It is encompassed by a stripe or thin layer of a brown coloured substance; and external to these there is another thin layer of a bright yellow colour.

The same distinctions of substances exist in the *guinea-pig*, the *rat*, and some other *saltigrada* quadrupeds, or rather a division into five substances, according to J. T. Meckel, who reckons every shade of colour as a distinct substance composing this gland.

It is remarkable that in the *elephant*, which has the cortical and medullary substances of the kidneys indistinct, the two substances of the renal capsules are so likewise, which marks the great analogy and connection which exist between the kidneys and these bodies. This is still further shewn by the renal capsules having a uniform colour and substance in birds, which want the distinction of cortical and medullary substances in their kidneys.

Plate VII. of the Anatomy of Mammalia, and *fig. 2*, shews the relative magnitude and form of the renal capsule and kidney in the *common rat*: *a* is the capsule to the kidney. *Fig. 3*, of the same plate, exhibits a section of the renal capsule of the *rat*, in order to expose its different coloured substances: *a* is the central substance; *b*, the intermediate one; *c*, the cortical or external substance. *Fig. 4*, is a section of the renal capsule of the *ox*, to exhibit the cavity in the interior; *a*, the vein of the capsule; *b*, the cavity.

Glands for peculiar Excretions.—The most of these in mammalia are situated in the neighbourhood of the anus, or the external parts of generation, and secrete an odorous fluid, the natural use of which appears to be that of a defence against hostile animals. Nevertheless, many of the products of the excretory glands are employed by mankind as perfumes, or as medicines. There appears to be a very considerable resemblance amongst these excretions of quadrupeds, not only in their colour and consistence, but their effects upon the sensations of other animals. The foetid matter furnished by the *pole cat*, and the *civet* or *myff*, are equally offensive to many individuals of the human species, and are probably universally disagreeable to beasts, except those that furnish them. All these odorous excretions likewise have a similar effect upon the nervous system, though differing in the degree of that effect.

In several quadrupeds, besides the small follicles which furnish the sebaceous matter of the prepuce, the odour of which is rather calculated to invite the opposite sex than to disgust other animals, there are two glands of considerable

MAMMALIA.

size on the sides of the penis, which are conglomerate and formed of different lobules united together, and producing a common excretory duct, which opens within the prepuce either of the penis or the clitoris. These are very remarkable in the *rat* tribe, in whom they are large, flat, oval masses of granular bodies.

Cuvier ranks the apparatus which furnish the *castor* amongst the glands of the prepuce, but they are much larger than would be necessary for the secretion of a substance to be used merely on the penis or clitoris. They are situated under the integuments, between the pubis and the common aperture of the anus and prepuce, which exits in the *beaver*. The number of these glands is apparently four; but there are two others involved in the lower sacs. The two first glands are conjoined together, and have, when thus united, the figure of a heart. Their internal coat is smooth, thin, and of an ash colour, streaked with some white lines. They contain a cavity internally, the parietes of which are thick, and formed into irregular folds or wrinkles, upon which a grey odorous substance is found to adhere. The ash colour of the external coat is derived from the inner one. These two glands or pouches measure across about two inches in each direction. Where they are applied to each other, there is an aperture of communication between them of an inch in size. Both glands discharge their contents into the prepuce by a single orifice.

Underneath these sacs there are two others, which are distinct, and have the figure of a pear, somewhat flattened. They are two inches and a half long, and about ten lines broad. There are placed, between their coats, a number of small glandular bodies, each of which contains a cavity, in which there is a fluid secreted, that is strongly odorous, yellow, unctuous, and combustible.

At the lower part of these pear-shaped pouches the third pair is found. They are about fourteen lines in length, and six in breadth. They are full of a fluid, which is yellower than the contents of the other glandular sacs, and has also a different smell. These pouches have likewise little glandular bodies on their surface, similar to those of the second pouches. The membranes of the two lower pair of pouches are intimately united to each other. Both these pair open into the common aperture of the anus and prepuce. An ancient error prevailed with respect to the *castor*: many of the old anatomists believed that it was taken from the testicles. Some absurd stories also are told of it; such as the *beaver* pressing this substance out with its paw, and eating it to create an appetite, &c.

The apparatus for the secretion of the musk in the *moschus moschiferus*, is perfectly similar in structure to that above described in the *beaver*. The pouch containing the musk is situated under the skin of the abdomen. Its figure is oval, and it is hollowed below into a groove, in which the penis comes forth; its parietes are apparently membranous, but the inner surface presents many irregular folds. The pouch has a small orifice, which is at the fore-part of the prepuce. The membrane surrounding it contains some sebaceous follicles. Between the pouch and the skin of the belly there is a fleshy substance, apparently glandular. The musk does not exist in the females, nor in the young males.

The *antilope gutturosa* has also been described by Pallas as possessing a similar membranous pouch to the foregoing, but it does not contain the musk. Most of the *antilopes* have a pouch at the side of each nipple, formed by a fold of the skin, which contains an oily, odorous matter.

The *inguinal* glands of the *bare* appear to belong to the class of those of the prepuce. They are small oval bodies; their orifices are on two semi-lunar spots of the skin, which

are deprived of hair, and are situated one on each side of the prepuce of the penis, or of the clitoris.

These glands, which Cuvier has called the *anal*, are capable of furnishing the most powerful of the odorous excretions. They are these which afford the substance called *civet*, and those offensive discharges of others of the *weasel* tribe, the effluvia of which scarcely any animal can bear to approach. These anal glands are two pouches of a round or pear-shape, the coats of which are glandular. The interior of the sacs is lined apparently by the continuation of the skin. They are the reservoirs of the odorous matter which is discharged by a large opening from each sac, usually into a cell or cavity formed by the integuments either around the anus, or in the neighbourhood of it. There are peculiar muscles for compressing these bags. Bartholinus figured four muscles; the French academicians found but three; one which passed across from one pouch to the other, and two muscles which arose from the ischium: each came to be joined to its antagonist at the middle of the two pouches, and was fastened to the pouch over which it went to make this conjunction. Cuvier merely represents some fasciculi, which cross between and surround the pouches. The odorous matter found in the *civet* bags is of a yellow colour, and resembles oil in composition and consistence. It has the smell of musk.

These kinds of anal glands are met with in many of the *digitigrade* and *saligrade* quadrupeds, and *seal* tribe; Blumenbach also ascribes them to the *opossums*. There are three of these pouches in the *marmot*, but smaller than the usual size: they open upon the edge of the anus, in the centre of three papillæ which project from the anus when the animal is excited.

In several quadrupeds, besides the stink bags above described, there are numerous small glands placed in the parietes of a large cell or cavity, which the integuments form either around the anus or in the neighbourhood of it, or, in rare instances, in other parts of the body. These frequently make a part of the excretory apparatus already described, but they exist also without the anal sacs, or stink bags.

In the *civet*, this cavity is situated between the genital organs and the anus: it opens by a longitudinal slit, the edges and inside of which are furnished with long hairs, that stand inwards. The inner surface of the cavity is grooved in the transverse direction.

The glandular cavity of the *ichneumon* surrounds the anus: the internal surface of it exhibits a great number of foramina along the margin. These are the orifices of the follicular glands, which are each about the size of a small pea, and lie upon the external part of the parietes of the cavity. They furnish a thick, yellow, oily fluid. On the superior part of the circumference of the anal cavity there is a triple row of little conglomerate glands, which secrete a whitish matter, and have larger openings than the preceding glands. This cavity further receives the contents of the large glandular sacs above described. The anal cavity is compressed by the usual sphincter ani.

The *guinea-pig* has a square shaped cavity below the anus. It is much puckered internally, and receives the product of two sebaceous glands, which has a peculiar smell.

The anal cavity in the *hyæna* has a narrow transverse opening. This slit, says Cuvier, leads first to two lateral pouches, which are the central cavities of two glandular masses composed of lobes and lobules. These two pouches communicate with two other glands, of which the lobules are more detached, and are even assembled round a central cavity, in which their excretory canals terminate, and which opens into

MAMMALIA.

into the first pouches, as we have mentioned. There issued from the left anterior pouch a yellow-brown matter, although that in the right held a grey matter, as well as the two posterior pouches.

In the *badger* there is a transverse fissure between the anus and tail, which is the mouth of a cavity, the parietes of which are furnished with a number of small glands, that secrete into it an unctuous fluid. It is this which the *badger* mixes with its urine, and with its tail throws against its assailants.

The *pecari*, or *Mexican hog*, has a large gland or pouch situated under the skin of the back. It is composed of lobes and lobules, the excretory ducts of which terminate in a single orifice in the back. This gland furnishes an odorous matter, and must be removed immediately after the animal is killed, it is said, to prevent the flesh being tainted with the smell.

There is a gland under the skin of the temple in the *elephant*, which secretes a viscid foetid matter, and should be ranked with those just described, though placed in a different situation. It has an oval shape, and is interiorly of a red, fungous structure. The fluid it secretes passes off by a canal, which descends obliquely from behind forwards, and opens midway between the eye and the ear. The parietes of the canal resemble the skin. The fluid of this gland is less abundant in females than males; in the latter it is very copious when the animal is in heat. After death it becomes like wax.

In the *antelopes* and *deers* there is a cell near the inferior and internal part of the eye; it is covered internally by a continuation of the skin, and is lodged in an excavation of the superior maxillary bone. The parietes of this sac are provided with sebaceous follicles which secrete a thick, black, unctuous substance. These sacs open by a slit. They have no connection with the lacrymal gland, or the tears, as has been supposed, but seem to belong, whatever may be their use, to the class of glands at present under consideration.

The *sheep*, and several of the *cloven-hoofed* quadrupeds, have glandular cavities in the feet. These are covered with hair internally, and have an excretory duct, which opens at the junction of the toes. When this is obstructed from wet weather, it occasions disease in the sheep.

In *fig. 6. Plate VII. of the Anatomy of Mammalia*, there is a view of the three different kinds of anal glands in the *ichneumon*. The letters *o* and *p* indicate the pyriform sacs; *q, q*, are the small glands which are upon the outside of the two-thirds of the cavity that surrounds the anus: these furnish the yellow unctuous fluid: *r, r*, are the conglomerate glands, situated farther in upon the anal cavity, and which secrete the whitish matter. Some muscular fasciculi are seen to pass between and surround the anal glands *o* and *p*, by which their cavities are compressed, and their contents forced into the common cavity that includes the anus, and receives the secretions of the three orders of anal glands in this animal.

Organs employed in the Exercise of the Generative Functions.

Male Parts of Generation.—The *penis* is a more complex organ in many mammalia than in man. The peculiarities in its formation do not correspond with a similarity of general structure in different animals, but are often perfectly specific, which seems to be designed, in some measure, to prevent that promiscuous intercourse which the blind appetites of some animals might lead to.

The penis has its figure and magnitude in many cases determined by the presence of a bone in it. The *os penis*, by

giving firmness and shape to the member, renders the corpora cavernosa and the glans less necessary: we accordingly find these parts diminished in those species which possess a bone in the penis.

The *os penis* has been found in some species of *monkey*, but not in others: in most of the *bat kind*, in the *bear*, the *badger*, the *raccoon*, the *weasel*, the *ichneumon*, the *otter*, the *dog kind*, except the *hyena*, the *cat kind*, the *hamster*, and several of the genus *mus*, the *seal*, the true *whales* amongst the *cetacea*. It is denied to the *lamantins* by Cuvier, but Blumembach states that it exists in the *walrus*. We possess a preparation of an *os penis*, which we have every reason to suppose belonged to that animal. It is two feet long, thicker than the thigh-bone of a man, and as solid as ivory, except at the root and where the glans is attached, at which places it is somewhat spongy in its texture. Camper is said to have a preparation of this bone, which had been fractured, as he supposed, during coition, for the penis of this animal is not exposed to injury unless when erected.

The *os penis* is grooved in the lower surface for holding the urethra in the *dog kind*. It ends in a hook in the *weasels*. It is curved into the form of an S in the *raccoon*. In the *squirrel*, it is spirally twisted at the extremity. It is large, rounded, and terminates like a club in the *whales*.

This bone forms the principal part of the penis in the *bear*, *otter*, *raccoon*, *badger*, *dog*, and *weasel*; but in the *bats*, *cat*, *ichneumon*, and most of the *rat kind*, it is small, and serves as an accessory part to the corpora cavernosa.

The direction and attachment of the penis are different from what is observed in man; none but the *quadrumanæ*, the *chiroptera*, and the *armadillos*, have the penis pendulous, or at all times projecting from the body, and covered with a skin proper to itself. In the other genera, the penis, when employed, is concealed more or less in a sheath formed by the skin of the abdomen. In the *carnivorous* and the *large herbivorous quadrupeds*, the sheath of the penis opens forwards, near the umbilicus. When the penis is long in these cases, it forms curves or folds upon itself in the sheath. According to Cuvier, the penis of the *elephant* makes, when retracted within the sheath, the curves of a double italic S.

Those quadrupeds which have the penis fixed in this manner under the belly, have two *adductor* muscles to the sheath: they arise from below the aponeurosis and the flesh of the abdominal muscles by several fasciculi, and having joined their fasciculi, are inserted into the sides of the anterior part of the sheath. These draw the sheath forwards upon the belly. There are also two muscles for *retracting* or opening the sheath, which come from the first caudal vertebra: they terminate in the *digitigrada*, either upon the external part of the corpora cavernosa, or upon the *os penis*; and in the *ruminants* they are inserted upon the sheath of the penis. In the former these muscles must bring back the penis itself.

In the *solipeda*, the retractor muscles accompany the inferior part of the urethra, and are lost in fasciculi that are distributed upon the muscle which covers this canal. In these animals Cuvier thinks the retractor muscles restrain the elongation of the penis when it is erected, and contribute to withdraw it into the sheath.

These muscles appear to be supplied in the *elephant* by the levators of the penis, to be described hereafter.

In some of the *saltigrade* quadrupeds, the penis comes first as far forwards as the anterior brim of the pubes, and then turns back, the orifice of the prepuce being near the anus. But in most of the *saltigrada*, and in the *opossums*,
the

MAMMALIA.

the penis goes backwards from the time that it comes out of the pelvis.

Several quadrupeds have been observed to void their urine backwards. It was, therefore, thought by the ancient naturalists, that they also copulated in the same direction, but later observations have proved the contrary.

The figure of the penis is very various in mammalia. It is determined either by the size and shape of the os penis, when that bone exists, or by the form of the glans, and the thickness of the corpora cavernosa. The penis is slender in the *boar* and *cloven-footed* quadrupeds. It is thick and long in the *solipeda*, the *elephant*, and the *lamantins*; thick and conic in the *porpoise* and *rhinoceros*; thick, conic, and flat in the *dolphin*; nearly cylindrical in the *monkeys* and *lemurs*; short in the *opossum*, and most of the *saltigrada*, the *digitigrada* and the *scail*; long and cylindrical in the *hedge-hog*; twisted like a screw in the *squirrel*, and bent like an S in the *raco.n.*

The corpora cavernosa are commonly formed of two distinct branches arising from the ischium, as in man, and afterwards joined apparently into one body; but the interior division of this part of the penis by a septum is often less distinct in mammalia, and sometimes is wanting. It is incomplete in some species of *monkey* and in the *lemurs*. It is totally wanting in the *bear* and the *badger*. It is also absent in most of the *many-hoofed* quadrupeds: the *elephant* and *rhinoceros*, however, have it. The *solid* and *cloven-hoofed* quadrupeds and the *cetacea* want a septum between the corpora cavernosa. In these cases the ligamentous laminae arise from within the circumference of the united cavernous bodies, and meet in the centre.

The corpora cavernosa in the *opossums* arise by two long small branches, which are only connected to the ischium by means of the muscles called the *erectores penis*. They unite without any septum, and then branch into two, in order to form the bifid penis of these animals.

In the *kangaroo* there are at first four corpora cavernosa, which unite to form a conical-shaped penis. The urethra runs in their centre. They are compressed by a muscular investment. The director muscles of the penis, or *ischio-cavernosi*, serve to connect two of the roots of the corpora cavernosa to the ischium. The two other roots are enveloped by a muscle which takes the place of the *accelerator urine*, or *bulbo-cavernosus*.

The interior of the corpora cavernosa, during the erection of the penis, has been described by Cuvier in the *elephant*, and other large quadrupeds, as being composed of the branches of the veins anastomosing frequently with each other, so as to form a close and inextricable plexus, resembling cells. We have discovered the spongy part of the urethra to be composed of ramified vessels in man and quadrupeds, but we have not been able to satisfy ourselves, that the corpora cavernosa are made in the same way.

The first membranous portion of the urethra is in proportion to the rest of the canal, commonly longer in mammalia than in man. The *monkey* kind have it short and almost entirely enveloped in the prostate gland: it is particularly long in the *hedge-hog*, *opossum*, *kangaroo*, *civet*, and the *cat kind*, in most of which it is more than half the entire length of the urethra.

The part called *verumontanum*, on which the seminal ducts terminate, contains in the *elephant* and some others a deep cell. There are frequently other folds of the membrane which form longitudinal eminences besides the *verumontanum*; and in the *marmots* these are twelve prominent folds, which go off on each side of the longitudinal projection.

The second portion of the urethra in the *cloven-footed*

quadrupeds and the *hog*, has a cul-de-sac at its origin, or at that part corresponding to the bulb. This cæcum receives the semen and the fluid of Cowper's glands. In the *squirrel* and *marmot*, the dilatation in the bulb merely receives the ducts of Cowper's glands, and is continued into a narrow canal, which opens into the urethra as far forward as the middle penis.

The spongy texture of the urethra in the *opossum* and *phascolumys*, all the *marsupial* quadrupeds, and in the *water rat*, arises in two branches distinct from each other, and inclosed in their proper muscle. There is also some appearance of two branches to the bulb in the *camel*.

There is a large corpus spongiosum in the *large herbivorous* quadrupeds, and a small one in the *carnivorous*, more particularly the *otter*, *bear*, &c. It is scarcely apparent at the part of the urethra which runs along the os penis.

The corpus spongiosum, as already mentioned, is composed of an intricate plexus of veins. This is very evident where it forms the glans penis of the *horse*, in which the vessels are very plainly seen. They likewise communicate with a vast mass of veins upon the dorsum of the penis in this animal, which increase the bulk of this member very much when they are distended with blood during erection.

The *glans penis* varies very much in mammalia, both with respect to form and the nature of its integuments: even the animals of the same genus do not agree in these respects.

The glans of some *monkeys*, as those with prehensile tails, forms a large tubercle, like the head of a mushroom. In the *baboons* and *apes* it is oval, and split into two tubercles at the end where the urethra opens. In the *Chinese ape* there are several tubercles, which produce a singularly formed glans.

In the *ring-tailed maucaeo*, (*lemur catta*), the glans is thick behind, but merely covers the os penis at the end. It is covered with horny spines, which have their points turned backwards.

The *vespertilio serotinus* has two tubercles or bulbs upon the sides of the glans. The inferior surface forms a sort of edge, and is clothed with stiff hair-like processes.

The *hedge-hog* has a piece of cartilage upon the top of the glans.

In the *racoon* the os penis has two tubercles at the end, which give the same form to the glans.

In the *cat kind* the glans is conic. The point is made by the os penis which projects beyond the orifice of the urethra. In most of this genus, the glans is armed with reflected sharp hard spines. Cuvier says they are few in the *lion*, and most numerous in the *Mexican cat* (*felis pardalis*).

In all the long-bodied or *vermiform* quadrupeds, and in the *badger*, *bear*, and *racoon*, the glans takes the form of the os penis.

In the *dog* genus, the back of the glans forms a very remarkable bulb of the shape of a chestnut, the base of which is posterior. It is composed of venous cells, which are only distended when the penis is erected, and is compressed behind the glans, there being two large trunks of veins running backwards, which carry off the blood from the bulb. It is by means of this apparatus that the penis of the *dog* is retained in the female organs, seemingly against his will. The sphincter of the vagina suffers a spasmodic contraction, and compresses the veins behind the bulb, and thus maintains it in a state of distention. To obviate the effects of compression upon the urethra, that part of the canal is lodged in a groove of the os penis. The semen of the dog passes in jets for some time after he has turned off, as it has been supposed, in consequence of his wanting vesiculae feminales.

In the *opossum kind*, the glans is necessarily bifid, as the corpora

MAMMALIA.

corpora cavernosa are so which it covers. The two branches of the glans penis are short, and are directed outwards in the *Virginian opossum*, but in the *Mexican opossum* and the *marmoset* (*didelphis murina*), they are long, and grooved upon the inner side so as to form a perfect canal when they are applied to each other. This canal forms a continuation to the urethra.

The *phascolonys* has the glans penis forming four lobes at the end: the urethra opens in the centre.

The *kangaroo* has a long, taper, sharp-pointed glans, formed chiefly by the corpora cavernosa. The urethra emerges near the end of the penis from the united corpora cavernosa, acquires the spongy coat, and ends in a kind of sac, which has its orifice under the point of the glans.

The formation of the glans, as well as all the other parts of generation, is singular in the *saltigrade* mammalia.

In the *guinea-pig* the orifice of the urethra is under a flat os penis; and behind and below it there is a cell, in the bottom of which are attached by their base two long hooks of a horny substance: the glans and surface of this pouch are covered with hard scales. When the penis is erected, the pouch is turned inside out, carrying with it the horny hooks, and forming a projection preceding considerably the orifice of the urethra. The glans is drawn in again by two fasciculi of muscles, which arise from the two crura of the corpora cavernosa, and pass under the bulb of the urethra, to which they are also attached. They furnish two tendons that run along the under part of the penis, and are inserted on the outside of the sac or pouch already mentioned.

The glans of the *agouti* is still more curious. It has a pouch similar to that above described, and horny scales upon the surface; and in addition to these, two horny plates upon its sides, which adhere to the glans by one edge, and leave the other edge notched like a saw.

The *alpine marmot* has the glans conical, and ending in a fine point, which is formed by the os penis. The urethra opens on the right side of this point, and on the left there is a small deep cell.

In the *common rat* there is the appearance of a second prepuce at the end of the glans, when the penis is not erected: this is produced by the edge of a cavity that encloses the os penis. This bone comes forth by pressure, and exhibits upon each side two little cartilaginous appendices, in the form of wings. The urethra opens under this extremity, and has upon the inferior edge a valve formed like a gutter.

The other species of the genus *mus* have the glans constructed upon the same plan: its surface is armed with papillæ, or with fine hairs, as in the *hamster*.

The *dormice* have a conical and sharp-pointed glans: the urethra opens at the end. There are two cells at its base.

In the *elephant* the glans is at first cylindrical, as the rest of the penis: the lips of the orifice of the urethra open to each side.

The glans of the *rhinoceros* has a singular conformation: it is dilated at the end like the mouth of a bell, in the centre of which there arises a peduncle, shaped like a mushroom, with a broad, flat, oval surface, upon the inferior edge of which the urethra opens.

In the *boar*, and many of the *ruminating* quadrupeds, the glans is taper and pointed, and has a fissure upon its side, in which the urethra terminates. The *ram* has it oval, with a transverse fissure at the end. The orifice of the urethra is at the left side of the slit, and near it there is a long slender process of a tendinous substance. The glans of the *camels*, which is long and taper, ends in a hard appendix, which is

bent transversely from left to right, by which its edge is turned forwards, and the point to one side.

The *solipeda* have a cylindrical glans, which contains a cavity or large cell, that is found to have a quantity of a brown oily substance, for defending the glans from the irritation of the urine, and lubricating the end of the penis. This secretion appears to be similar to that of the glands surrounding the glans in other animals, but is in greater quantity in the *horse* than in them. There is a second cell, according to Mr. Clarke's description, which is smaller than the first, and separated from it by a membranous partition: it nearly surrounds the urethra, which opens at the end of a pyramidal eminence of the glans.

The *northern lamantin* has the glans and all the penis similar to that of the *horse*, according to Cuvier, except the existence of a bone; although he denies that the *lamantins* have an os penis in another place.

The glans of the *porpoise* is broad at the base, diminishes suddenly, and ends in a slender point, at which place the urethra opens. In the *dolphin* it is broad, conic, and flat. The canal of the urethra runs distinctly along its under surface, and opens at its extremity.

The muscles of the penis are commonly more numerous in mammalia than the human subject.

The *erectores penis*, or, as they are more properly called by Cuvier, *ischio-cavernosi*, do not materially differ from those of man, except in the *marsupial* quadrupeds: they, however, vary with respect to strength. Cuvier has observed them to be particularly thick in the *lion*; they are weak in the *horse*; and are divided in the *elephant* into four distinct slips. In the *opossum* tribe these muscles form an oval mass around the roots of the corpora cavernosa, which in these animals are not attached immediately to the bones of the pelvis. The bulbous enlargement of the muscles is made of several layers of concentric fibres, which surround and compress the long roots of the cavernous bodies. The origin of the muscles is from the ischium by tendon.

The *accelerator urinæ* (*bulbo-cavernosus* of Cuvier) varies generally in thickness, in proportion to the difficulty of ejecting the urine and semen, as depending upon the structure of the urethra. In the *horse* this muscle is not confined to the bulb, but forms a layer of transverse fibres, which cover the urethra the whole way to the glans.

The *bulbo-cavernosus* consists of two portions in the *rats*, all the *marsupial* animals, the *elephant*, and the *camel*. In the two first tribes, these cover the branches of the bulb, and also extend to the corpora cavernosa and pelvis: they are, therefore, not strictly muscles of the urethra in these animals. The bulb of the urethra is single in the *elephant* and *camel*, notwithstanding its muscle is double.

The *bulbo-cavernosus*, in some instances, has no effect upon the urethra; the contents of that canal being expelled by a strong layer of muscle that surrounds the first portion of the urethra. Thus in the *marmot* and *squirrel*, the *bulbo-cavernosus* compresses the cul-de-sac of the urethra, into which the fluid of Cowper's glands is poured; and in the *ichneumon*, this muscle constitutes rather a thin layer, which surrounds both the glandulæ Cowperi, and performs no other office than that of expressing the fluid from these bodies.

Many mammalia have a muscle for raising and sustaining the weight of the penis. It has been described in the *baboons* as composed of two thick fleshy portions, arising from the arch of the pubis: its tendon is extended along the back of the penis; and towards the extremity it becomes incorporated with the corpora cavernosa. In the *barc*, *marmot*, *cavy*, &c. it is twisted backwards, in order to give the

MAMMALIA.

the proper direction to the penis during coition. This muscle is remarkably large in the *elephant*: it is attached to the pubis by two distinct fleshy portions, and partly to the roots of the corpora cavernosa; they proceed upon the dorsum of the penis, and their tendons uniting into one, it runs in a strong ligamentous sheath to the end of the penis. There is no muscle of this kind in the *horse*, which is the reason that manual assistance is given to that animal in coition.

In the *bear*, *raccoon*, the *dog*, &c. there is a small muscle arising from each of the roots of the corpora cavernosa, and conjoined by a middle tendon, which is inserted into the back of the penis under the pubis. This muscle compresses the dorsal vein in the *simia callitrix*, in which animal the middle tendon is not found.

In the *bisulca* there is a muscle on each side, which arises from the tuberosity of the ischium, and ascends obliquely inwards, and is inserted into the bulbous part of the urethra. It brings the bulb downwards and forwards, and contributes, as Cuvier thinks, to elongate the penis.

The *arteries* and *veins* of the *penis* are similar in mammalia and man, except where there are plexuses formed, as already described.

The *nerves* of this member are stated by Cuvier to be very large. He discovered that they formed in the *elephant* a net-work upon the veins of the back of the penis, in the same manner as they have been observed to do on arteries.

The *ornithorhynchus* and *echidna* seem to form a link between mammalia, birds, and reptiles, with respect to their anatomy. Their alliance with the two last mentioned classes is decidedly shewn in the structure of the organs of generation.

These two animals have a spur upon the heel of the male, for the purpose of holding the female during copulation. The spur contains two small bones or phalanges: one is very short, flattened, and joined to the astragalus; the other is long and pointed, and serves as the mould of the horny spur, in a manner similar to the spurs of *cocks*. There is no other instance in mammalia of the male possessing any prehensile organ, exclusively designed to be employed during coition.

The *penis* of the *ornithorhynchus* and *echidna* is attached to the margin of the cloaca, as in birds and reptiles. It is covered with the continuation of the lining of the cloaca, and is composed interiorly of a plexus of blood-vessels, which become more close and intricate towards the extremity of the penis. This plexus makes up the whole bulk of the organ: it is only surrounded by a fibrous sheath, and the integuments already mentioned. There is no urethra in the penis of these animals; that canal terminating short of it, as will be presently shewn. The penis is nearly cylindrical in its form, and short: it terminates in the *echidna*, in four eminences or processes, which are hollowed out in the centre, like cups. These correspond to the glans of other mammalia, and no doubt are endowed with a greater sensibility than the rest of the organ. Cuvier thinks the concavities of these eminences or papillæ are unfolded during erection. In the *ornithorhynchus paradoxus* the penis terminates in two papillæ, which have denticulated edges; and the surface of the penis is more rough and wrinkled than in the *echidna*.

The erection of the penis in these animals is accomplished by the distension of the vascular structure of the interior part of the organ, and by the contraction of the sphincter muscle of the cloaca. The penis is retracted by a particular muscle, which arises from the sphincter ani, and passes along the

under surface of the penis, and is attached to its extremity. When retracted, it is received into a sac.

The urethra in these animals is simply a muscular canal, continued from the bladder to the under part of the cloaca, into which there is a small round hole, not quite at the extremity of the urethra; that canal terminating in a sort of cul-de-sac. The *vasa deferentia* open into this canal at the neck of the bladder. There is a layer of muscular fibres arranged obliquely, and meeting upon a middle line, like the constrictors of the pharynx, which encompasses the rectum and urethra together, and assists the muscular coat of the urethra in ejecting the semen and urine into the cloaca.

There are two small oval bodies, containing each a cavity, from which there departs a long excretory duct to the side of the cloaca when it opens. These glands appear to correspond to *Cowper's*.

The margin of the anus is furnished with a row of well marked *follicular glands*, similar to those described in *birds*.

The *testicles* are originally formed and situated in the lumbar region, next the kidneys, in all mammalia, and in man. In some of the former they remain in that situation during life, as instances of which we may mention the *ornithorhynchus*, the *echidna*, the *elephant*, the *daman*, the *nectopodous* or *seal* tribe, and the *cetacea*. These animals are consequently without a *scrotum* and *cremaster* muscles. The testicles are retained in their proper situation by peritoneum, in the same manner as the other abdominal muscles.

In a number of mammalia the *testicles* leave the loins, and are placed behind the opening of the abdominal ring, which is so large that these bodies can easily pass backwards and forwards through it, as occasion may require. The testicles have been observed to come out of the abdomen in this manner, particularly in the season for pairing, in the *bat*, *mole*, *shrew*, *hedge-hog*; in many of the *murine* tribe, as the common *rats*, *hamster*, *muskrat*; and in the *guinea-pig*, *porcupine*, *beaver*, *squirrel*, &c. In these animals the passage from the abdominal cavity to the tunica vaginalis is permanently open, and of great width.

The situation of the testicles is subject to vary in mammalia, when they are on the outside of the abdomen: thus they are suspended in a single bag or *scrotum*, behind the penis, in the *quadrumania*, the *digitigrada*, and many *plantigrada*. The *scrotum* is long, and suspended before the pelvis, and wants the *septum scroti*, in the *opossum* kind, the *kangaroo*, and *phascolumys*. The scrotum forms two distinct pendulous bags in the *hare*, *jerboa*, and most of the *cloven-footed* and in the *solid-hoofed* quadrupeds.

The figure of the testicles varies but in a few species from that observed in man. The *raccoon*, *badger*, and *elephant*, have these glands of a globular form; and in the *nectopodous* and *cetaceous* tribes they are very much elongated.

The magnitude of the testicles is remarkably great in the *mole* and in the *saligrada* quadrupeds, being even more considerable than that of the kidneys. In these, and in several other quadrupeds, the testicles become much larger at the season for procreation than they are at other periods.

The interior structure of the testes in man and mammalia is essentially the same. In most of the latter that have been examined, the *tubuli seminiferi* are in separate packets. In the greater number of the *saligrada*, however, they are distinct from each other, and are very large. In the *ram*, the seminiferous tubes have been observed to be very distinct, and to have a serpentine or undulating course.

In several quadrupeds the real structure is clearly seen of the part called *corpus Highmori*. It is not a canal, nor does

MAMMALIA.

it possess the structure described by the older anatomists; but is formed by the *tunica albuginea*, and passes like a ligamentous stripe or band along the testicle, from which the laminæ or fibres that pass downwards and separate the seminiferous tubes of this gland arise. The principal arteries also of the testicle are sustained by this band.

The *epididymis* is very large in the *saltigrada* and the *echidna*; in most of the former and in the *opossum* tribe, it is not attached along the back of the testicle, but is free, except at its origin.

The *vasa deferentia* have thinner parietes in those animals that retain the testicles always in the abdomen, than in those instances where they occasionally pass into the scrotum, or are always outside the belly. They likewise proceed less directly to their termination in the urinary passage; thus in the *elephant*, the *echidna*, the *daman*, and the *ant-eaters*, their course is very tortuous.

Very frequently the *vasa deferentia* become thicker, or are dilated before their termination. In the *otter* and *seal*, and in many of the *saltigrada*, as the *hare*, *cavy*, *beaver*, *hamster*, and the *rat* tribe, these tubes acquire strength, and in the *saltigrada* just mentioned, they are also wider as they pass behind the bladder. In the *bear*, *badger*, and *raccoon*, their coats are much thicker, and the two *vasa deferentia* touch each other, and appear as one canal, but do not really communicate. In the *elephant*, the *vasa deferentia*, where they pass beside the vesiculæ feminales, are dilated into globular sacs, the surfaces of which adhere to each other. The *vasa deferentia* of the *horse* are dilated to about the size of the human thumb, for five or six inches before their termination. This dilated part consists of a number of cells, resembling those of the corpora cavernosa of the penis, which, when pressed, pour out a milky fluid. Mr. Bracy Clarke states, that the *vasa deferentia* run in the centre of these cells, with each of which they communicate by small pores. See *ANATOMY of the Horse* in this dictionary.

There is a similar dilatation in the *vasa deferentia* of the *ram*, in which there are transverse laminæ that form a mesh work.

The *vasa deferentia* are still more dilated in the *buffalo* than in the *ram* or *horse*. They are not divided into cells or meshes, but there are little cavities that secrete a fluid. They are dilated also in the other *ruminants*. The design of this structure seems to be to add a peculiar secretion to the semen before it passes into the urethra.

Cuvier mentions a curious variety in the course of the *vasa deferentia*, from the scrotum into the pelvis, in the *Chinese monkey* (*Simia sinensis*.) In this animal, that canal does not pass through the abdominal ring, but through the crural arch, and ascends between the internal and external oblique muscles to join the *cremaster* muscle near the ring.

In a very few instances, the two *vasa deferentia* have but one opening into the urethra. In the *badger* they terminate in a cul-de-sac, which contains the verumontanum.

The *vesiculæ feminales* are wanting in the following mammalia, viz. in all the *plantigrada*, except the *coatis* and the *hedge hogs*; in all the *digitigrada*; the genus *didelphis*, the *ornithorhynchus*, and *echidna*; the *cloven-hoofed* quadrupeds; in the *seal* tribe, and the *cetacea*.

The vesiculæ feminales are nearly similar in the *monkey* and the human subject.

In the *vampire bat* they are large, and form three convolutions. The first third of their canal is without cells or reticulation, and opens into a round body which is situated upon the neck of the bladder, and has the interior divided by membranous laminæ into a great number of cells, which are found filled with a seminal fluid. This cellular reservoir

also receives the *vasa deferentia*, and has two small openings into the urethra. The remainder of the tube of the vesiculæ is cellular, as usual.

In the *common bats* they are round white sacs, with a simple cavity: their coats are glandular.

In the *hedge-hog*, the vesiculæ appear as bundles of convoluted tubes; usually four in number on each side of that part of the urethra which contains the verumontanum; each of these bundles of tubes ends in one tube, which either opens separately, or conjointly, with that of some of the other bundles or parcels in the verumontanum. These different bundles or vesiculæ, when taken together, exceed in bulk that of the two testicles of the *hedge-hog*.

The vesiculæ of the *guinea-pig* are two long conical tubes, becoming much thinner towards the extremity: they have some dilatations in their second half.

In the *agouti* they are also large tubes, and have some smaller branches.

In the *marmot of the alps* the vesiculæ are small; their cavity is very intricate, and their coats glandular. They are similarly formed in the *bobac*, according to Pallas; but he describes the vesiculæ of the *suslic* (*mus citellus*, Pall.) as being composed of a little puckered tube, which adheres to a mass formed of smaller tubes.

The *rat* tribe have the vesiculæ feminales enormously large, particularly during the season of procreation. They project even beyond the pelvis. They are membranous bladders, conical in their figure, but twisted, and having their cavity rendered unequal by dilatations on their convex edge.

The *common hare* and *rabbit* have one sac in place of the vesiculæ feminales. This is of a considerable size, and of a rectangular figure. The external corners are sometimes extended from the body of the sac, and represent the two vesiculæ. The coats of the sac are membranous, except in the two-thirds of their superior side, which are very thick and glandular, and similar to the substance of the prostate gland. The opening of this sac into the urethra is single. In the *lepus pusillus*, *ogotona*, and *alpinus* of Pallas, the vesiculæ are two, and separate, as in other animals.

In the *squirrel* the vesiculæ are small, wrinkled, convoluted tubes, with glandular coats.

In the *daman*, according to Cuvier, the vesiculæ are very large and ramified.

The *rhinoceros* has the vesiculæ making two tolerably large bladders: their cavity is irregular, from a number of dilatations on their external side.

In the *boar*, the vesiculæ are remarkably large, and composed of lobes and lobules which contain cells interiorly, that communicate with each other. All the lobes pour out their contents through a common canal, which opens in the verumontanum.

The vesiculæ feminales of the *elephant* are very large. Their figure is nearly oval, there being a contraction which separates the top from the rest of the sac. The internal surface of the top and middle portions is provided with irregular columns or projections of the internal membrane of the vesiculæ, which is much thicker towards the top or end of the sacs than elsewhere. The vesiculæ are furnished with a muscle for expressing their contents in this animal. It arises from the neck, and extends as far as the middle part of the sac, its fibres spreading as they proceed.

In the *horse* and *ass*, the vesiculæ are two long membranous bladders, like portions of an intestine. They are wider at the end or fundus than the neck, which ends in a large excretory canal, that opens into the urethra by a common orifice with the *vas deferens*.

MAMMALIA.

Some anatomists have supposed that the prostate glands of the *cloven-footed quadrupeds* were the vesiculæ feminales. The only part corresponding to the vesiculæ in these animals, is a ligamentous bridge extending between the ends of the two vasa deferentia, and serving to unite the bases of the prostate glands. This ligament has been observed in the *ram*, the *axis*, &c. But in the *fallow deer*, the place of the ligament is taken by two little capsules, which appear to be glandular, and their cavity to lead to the verumontanum, by the same orifices with the vasa deferentia.

The parts supplying the place of the *prostate gland*, are very different in their structure and number in different genera of mammalia. The termination of the prostatic duct or ducts also is various; they are found to open into the origin of the urethra, or throughout its extent, or towards the end of that canal. In some of the *saltigrada*, in the *hedge-hog*, and in the *mole*, the parts corresponding to the *prostate glands* are described by Cuvier as a distinct series of glands, which he calls *vesicules accessoires*, on account of their having a structure similar to that of the vesiculæ feminales, and because they are observed to enlarge during the season of procreation; but their being found in those animals which have not prostate glands of the usual structure, and yet are remarkable for the magnitude of all the genital organs, would lead us to receive these vesicular bodies as analogous to the prostate glands of other mammalia; we shall therefore describe them as such in the proper order of the animals to which they belong.

The prostate gland in the *monkey* tribe is similar to that of the human subject, except that it is somewhat different in shape. In the *mandril*, there are some additional lobes to the prostate.

This gland in the *lemurs* has two offsets, which surround the excretory ducts of the vesiculæ feminales. There are two in the *lemur tarsius*, which form distinct tubercles before the vesiculæ upon the sides of the urethra.

In the *vampire bat*, the prostate is simple, as in *man* and the *monkey*; but in the *common bats*, this gland consists of a great number of lobules.

In the *bear*, the substance of the prostate appears to be confounded with the enlargement of the united vasa deferentia.

In most of the *vermiform quadrupeds*, as they are called, such as the *weasel*, and in the *otter*, this gland appears like a layer upon the urethra. In the *ichneumon*, however, it is of a considerable size.

The *hedge-hog*, as before observed, is one of the animals which has the prostate formed of a number of tubes. It has four bundles of these tubes, which are smaller than those of the vesiculæ feminales, and arranged parallel to each other, branching into still smaller tubes.

In the *mole*, this gland is also composed of a mass of tubes, ramified and convoluted upon each other. During the season for copulation, these tubes enlarge so much, that they form a bundle, according to Cuvier, of a greater bulk than the urinary bladder.

In the *agouti* and *guinea-pig*, the prostate is formed of ramified and convoluted tubes. The former animal has these tubes ending in vesicular processes.

The *rat* tribe and *lagomys* have also tubular prostates, and in addition to them have two glands, which are attached to the inner surface of the vesiculæ feminales. They are composed chiefly of one tube.

In the other *saltigrada*, the prostate gland is a single mass, often divided posteriorly into two lobes.

The prostate is single also in the *digitigrade* and *pedimanous quadrupeds*, as far as they have been examined.

In the *boar*, it is divided into lobes, and there is besides a layer of glandular substance, which surrounds the origin of the urethra.

The *elephant* has four prostate glands, which are small in proportion to the other parts of generation. They are of different sizes with respect to each other. Some muscular fibres are spread over them which serve to press out their secretion. Each gland contains one principal cavity, with which smaller cavities communicate: these last fill the indistinct lobes that are seen upon the glands externally. The chief cavity of each gland produces a duct, and these ducts terminate separately at the side of the verumontanum.

The *cloven-hoofed quadrupeds* have two prostates possessing the same cellular structure as those of the *elephant*. The lobes are still more distinct in the *ram* and *bull*.

There are four prostate glands in the *solid-hoofed* order. The two first are paler, and have larger cavities than the others. They are covered with muscular and tendinous fibres, which are extended to them from the vesiculæ feminales and the bladder. The ducts from this pair of glands have many orifices in the urethra. The second pair of prostates are situated towards the end of the membranous portion of the urethra. They are enclosed by muscular and tendinous fibres. They have each twelve ducts, which open by as many orifices, arranged in a row in the urethra.

The *seal* tribe have the same sort of prostate as that described in the *otter*.

The *cetacea* have the prostate in a single mass, and cellular internally, as in the human subject, &c. The muscle which surrounds it is very strong.

The glands called *Cowper's* are much larger, and consequently of more importance, generally, in mammalia than in man. They are wanting in some genera, and present in others closely allied to them. These glands, therefore, as well as the vesiculæ feminales and prostate, are not subject to any general rule, or regulated, either as to their existence or magnitude, by the anatomical rank or character of the animals. Cowper's glands are not found in the *bear*, *raccoon*, *hedge-hog*, *mole*; and are wanting, according to Cuvier, in all the *plantigrade*, except the *ichneumon*; in the *dog* genus; the *vermiform quadrupeds*; in the *hare* and *rabbit*; in many other of the *cloven-hoofed* tribe; the *horse* and *ass*; in the *seal*, and in the *whale* tribe.

These glands become larger than in man, in proportion to the size of the animals, in the *quadrumanous* and *chiropterus* mammalia.

They are also very large in the *civet* and *cat*; of a still greater size in the *hyana*. The muscle that surrounds them in these animals is very thick.

In the *ichneumon*, the glands of Cowper are very remarkable. They are covered by a layer of muscle, and each of them is besides enclosed in a musculo-tendinous sac. Each gland consists of a number of vesicles, which communicate with each other, and furnish a single excretory duct, that runs along the lower part of the urethra, and terminates by a distinct opening in the bottom of the cell at the end of the penis, in which also the urethra itself finishes. These glands have an egg shape, and are of great size.

In the *marsupial* animals there are several Cowper's glands, and it is remarkable that they are never wanting in this tribe, although the other glands are in some of the genera. The *Mexican* and *Surinam opossums* (*didelphis cayopolin*, *d. orientalis*), the *phascolumys*, and the *great kangaroo*, have six Cowper's glands. The *kangaroo rat*, and *Virginian opossum*, have four. In all these animals they are composed of tubes which lie in the longitudinal direction of the glands.

In the *echidna*, there is a gland analogous to Cowper's

MAMMALIA.

on each side of the cloaca. They are small oval bodies, containing a narrow cavity internally, from which a long duct proceeds. It passes through the constrictor muscle of the cloaca, and goes to join the little canal by which the urethra opens into the cloaca. These glands are surrounded by a very strong muscle, which urges their fluid out when occasion requires.

The *squirrel* has two large vesicles, cone-shaped, and coiled upon themselves. The top of these has thick glandular coats, and is divided, interiorly, into a number of little cells. The glands both open into a cavity in the bulb of the urethra, which is continued into a canal that extends to the bend of the penis when it opens into the urethra. The *alpine marmot*, and the *bobac*, resemble the *squirrel* in the structure of their Cowper's glands.

The *boar* has these glands in the form of long flattened cylinders. Their substance has a firm texture; it contains small cells, which open into larger ones, and they again join to form a common cavity, from whence a canal proceeds to open upon the side of the urethra, within the bulb. Their muscle has oblique fibres. The glands of Cowper are very large in the *elephant*, in proportion to the prostates, as before-mentioned. They have an irregular form, as if lobulated. There is a distinction of two portions to be observed: the first is situated next the bulb of the urethra, and is small: it is divided internally into cells, which are of different sizes, the smallest being external, and the larger opening at last into a common cavity in the centre of this part of the gland, which furnishes a duct to join the principal duct that comes from the rest of the gland. The larger portion of the gland contains two central cavities, which each give origin to a duct. These two ducts concur to form the principal duct above-mentioned. It proceeds, for some way, in the parietes of the urethra, before it opens into the canal. The glands of Cowper have a very thick muscle in this animal; the fibres of which are collected upon a tendon that is attached to each side of the corpora cavernosa.

In the *camel*, the glands of Cowper resemble, in figure and size, pigeon's eggs; their texture is close: and their single excretory duct terminates within the bulb of the urethra. The same structure is observed in the other *cloven-hoofed* quadrupeds which possess these glands. The muscle for compressing them in this tribe is very strong.

The figures which illustrate the *male organs* are found in *Plates VII. and VIII. of the Anatomy of Mammalia.*

Fig. 7, in Plate VII., exhibits the os penis of the *dog*: *a* points out the groove in which the urethra is inclosed for some distance. *Fig. 8, of the same plate,* is a view of the os penis in the *squirrel*. *Fig. 1, in Plate VIII.,* shews a transverse section of the penis of the *kangaroo*, in which the canal of the urethra, as indicated by *a*, is seen in the middle of the united corpora cavernosa. *Fig. 2, of the same plate,* is a similar section of the *kangaroo's* penis nearer the end, in which the urethra is seen to be gaining the side of the penis. *Fig. 3, of the same plate,* is a longitudinal section of the penis of the *dog*, after the cellular structure had been injected with quicksilver, dried, and emptied: *a*, the glans penis; *b* is the bulb behind it; *c, c,* the trunks of the veins going backwards from the bulb, which are compressed by the sphincter vaginæ of the female during the coitus. *Fig. 4.* is a view of the penis of the *guinea-pig*: *a* shews the glans, armed with horny scales; *b* are the hooks that come forth from the pouch in which the urethra terminates; *c, c,* the muscular fasciculi that retract the pouch. *Fig. 5.* is the penis of the *cat*: *a*, the glans furnished with reflected horny spines. *Fig. 6, of this plate,* represents the male organs of the *kangaroo*; *s* is the urinary bladder; *g*, the ureters; *r*, the vasa

deferentia; *p*, the first part of the urethra, which is inclosed in the prostate gland; *a, b,* and *c,* are the three glands of Cowper, on each side; *d, d,* are the two branches of the bulb of the urethra, each enveloped in its proper muscle; *e, e,* are the two branches of the corpora cavernosa, inclosed by their muscles; that on the right side is laid open longitudinally to expose its interior, and the section of the muscle; *g* is a portion of the sphincter; and *k* is a portion of the levator ani muscle; *i*, the rectum; *l*, the anus; *o* is the pointed glans of the penis. *Fig. 6, of Plate VII.* exhibits the male parts of the *ichneumon*: *a* is the bladder; *bb*, the ureters; *c, c,* their orifices in the neck of the bladder; *d, d,* are the vasa deferentia; *e, e,* their orifices in the urethra; *f, f, f, f,* the different lobes of the prostate gland; *b* is Cowper's gland of the left side exposed, the muscular fac in which it is inclosed being laid open; *i*, the opposite gland, covered with its muscle; *k* is the excretory duct of the left Cowper's gland; *l*, an opening seen at the lower part of the glans penis, which leads into the cell where both the urethra and excretory ducts of Cowper's glands terminate; *m* is a part of the ischio-cavernosus muscle of the right side; *nn*, the rectum, at the lower part of which the anal glands are seen, which are already described and referred to under the head of the *excretory glands* in this article. *Fig. 7, of Plate VIII.* exhibits the male organs in the *phacocolomys (didelphis ursina* of Shaw): *a*, the urinary bladder; *b, b,* the ureters; *c, c,* the vasa deferentia; *d, d,* the testes, of which the one on the left has the tunica vaginalis slit open; *k*, the first portion of the urethra; *l, l,* the branches of the corpora cavernosa enveloped in their muscles; *m, m,* the branches which form the bulb of the urethra, covered also by muscle; *n, o,* two of the glands of Cowper, seen on each side; the third are concealed by the branches of the bulb of the urethra; *q* is the glans penis; *r, r,* the retractor muscles; *s* is the rectum. *Fig. 5, of Plate VII.* is a view of the organs of generation in the male *echidna hystrix*; *a, a*, the singular termination of the penis in this species; *b*, the body of the penis; *c*, the cloaca; *d, d,* the rectum, slit open and divided, to shew the canal which conducts the urine and semen to the cloaca; *g* is that canal laid open; *f, f,* orifices of glands; *e, e,* Cowper's glands; *k*, urinary bladder; *i*, its opening into the urinary canal; *ll*, the vasa deferentia; *nn*, the epididymis of each side; *m, m,* the two testicles. *Fig. 8, in Plate VIII.* represents one lobe of the vesiculæ seminales of the *hedge-hog*, which is seen to be composed of convoluted tubes. *Fig. 9, of the same plate,* shews the single vesicula seminalis of the *hare*; *a*, the penis; *b*, the urinary bladder; *c*, the vesicula, with its two horn-shaped processes. *Fig. 10.* is a view of one of the lobes of the prostate, or, as Cuvier calls it, accessory gland of the *hedge-hog*.

Female Organs of Generation—The orifice of the *vulva* is not provided, in mammalia, with either the *external* or *internal labia*. It is a simple fissure in most cases, taking the direction of the body. The *hyæna*, however, has this slit placed transversely. In the *saltigrada*, the orifice of the vulva is circular, and in many of them, and in the *marsupial* animals, it is surrounded by a sphincter, common to it and the anus.

The *vulva* is not a mere entrance to the vagina, as in the human subject, but forms most commonly a canal of some length, preceding the true vagina. In the *prehensile-tailed*, and other American species of *monkey*, this canal is, according to Cuvier's observations, as long as the vagina. In the *bear*, it is even much longer. In some cases, however, the vulva is little more than the aperture of the vagina. It has been observed to be so in the *lemur*, the *agouti*, *paca*, and *guinea-pig*. In the *baboon* also, it is a very shallow cavity.

MAMMALIA.

The internal surface of the vulva has usually slight rugæ, which disappear upon the part being stretched. In the *tiger* they are oblique in their direction, and very small. They are transverse in the *bifulca* and the *hyæna*, in which they are numerous, fine, and undulating. The *daman* has the interior of the vulva smooth. There are glands analogous to those of Cowper, the ducts of which pass into the sides of the cavity of the vulva. These glands are remarkably large in the *cat* genus and *marfupial* tribe of mammalia. They are compressed by a muscular investment.

The *clitoris* of mammalia is of various figures, sizes, and structures.

Its situation in all quadrupeds is necessarily the reverse of that in the human subject: the part of the vulva next the pubis being the lowest in all animals whose station is on four legs.

The clitoris is situated farther in where the vulva forms a canal, than in other cases. In the *bear* it is inclosed in a pouch, which opens into the vulva by a small orifice. In the *baboon*, and in the *rat* tribe, the clitoris is situated externally to the vulva: in the latter animals, the skin before the vulva forms a projection, which serves as a sort of prepuce to the clitoris, at which place also the urethra terminates; there are, therefore, in the *rats* three apertures in succession; the orifice of the urethra, the opening of the vulva, and that of the anus.

The clitoris of quadrupeds so generally resembles the penis of the males in the same species in form and structure, that it has been supposed they were similarly constructed in every instance. There are, however, exceptions to this rule: the clitoris in the *quadrumana*, the *civet*, and the *dog*, wants a bone, although there is an os penis in these animals.

The size of the clitoris is frequently greater in proportion than in the human subject: it is particularly so in the *monkeys*, *lemurs*, most of the *digitigrade* and *saltigrade* quadrupeds. It is very long, and curved upon itself, in the *bear*. In the *marfupial* mammalia, which have a bifid penis, the clitoris is also double.

The prepuce of the clitoris sometimes forms a deep sac, in which the latter is nearly concealed, as in the *dog* genus. This prepuce is furnished with numerous sebaceous glands, like those of the penis, and in the *rat* kind they are extremely large.

The *orifice of the urethra* is found pretty uniformly upon the extremity of the inferior part of the vulva; it is, consequently, often much deeper seated in mammalia than in the human subject.

In the *prehensile-tailed monkeys*, and some others of the new continent, the urethra opens in the substance of a strong fold, extended from the hymen. Sometimes this canal is found to open in a slit between two tubercles, or folds, of the inner membrane of the vulva, which are sometimes extended upon the sides of the groove on the back of the clitoris, to conduct the urine out. In other cases, the urethra opens in the middle of a papilla. This orifice is in the base of the clitoris in the *agouti* and *paca*; but in the *lemurs*, properly so called, and the *lori*, the urethra passes along the back of the clitoris, and opens near its end.

A general opinion has prevailed that the *hymen* is peculiar to the human subject, which seems to have arisen from supposing this part to be formed for the sole purpose of proving the virginity, and, consequently, the purity of the mind in the female of the human species. Similar obstacles, however, to the congress of the sexes, are found in a considerable number of mammalia, and probably exist in many other species that have not yet been examined for this circumstance.

In the *simia paniscus*, and *striated ape* (*simia jacchus*), the *hymen* consists of two semi-lunar folds of membrane, the pointed corners of which unite, above and below, on two columns of the superior and inferior parietes of the vulva. These folds were found to be nearly effaced in an *old monkey* (*simia paniscus*).

The *northern lamantin* has been described by Steller as having a strong semi-lunar membrane situated at the inferior part of the opening into the vagina from the vulva.

Cuvier found a very decided membranous partition of the vulva from the vagina in a young *daman*. It was a circular fold of thin membrane, nearly of equal breadth at every part. The same author discovered in the *brown bear* a thick fold of the internal membrane, which projects in such a manner from above, as to convert the aperture of the vagina into a simple transverse fissure.

In the *hyæna* there is also a thick broad fold of membrane, which forms two sinuosities, the one above the other, projecting from the side of the vulva, and having the figure of a beak, between which there is a narrow transverse slit, that leads from the vulva into the vagina.

The *otter*, the *bitch*, the *cat*, and the *clowen-hoofed* quadrupeds, have been observed to have the vulva separated from the vagina by a membranous circle, which approximates, or unites, either directly, or by means of little transverse bands, the longitudinal folds of the vagina that arise from this circle.

The *vagina* varies very much with respect to its size. This is chiefly regulated by the length of the vulva, and the magnitude of the fœtus.

It is usually less wide than the vulva in those mammalia which have not had any young.

The length of the vagina, in proportion to that of the vulva, varies in different species of the same genus: thus, in the *prehensile tailed monkeys*, and some other *simiæ*, it does not exceed the vulva in length, but in the *baboons* it is much longer.

The *vagina* is about half the length of the vulva in the *brown bear*. It is twice the length in the *cat* and *dog* genera. In the latter there is a remarkable dilatation, which is adapted to hold the bulb of the *dog's* penis.

There are generally longitudinal rugæ to be observed upon the internal surface of the vagina. The structure of the vagina is very curious in the *bears*. The longitudinal rugæ are intersected by deep fissures, which divide them into ridges. There is one circular fold that entirely conceals the *os uteri*. It has a crucial opening, or one in the form of a T, which does not altogether correspond with the orifice of the uterus. This structure, added to the form of the hymen already mentioned, must produce great obstruction to the reception of the male *bear*, and to the passage of the semen into the uterus.

The rugæ of the vagina are transverse in the genus *delphinus*, and in the *hyæna*, although Blumenbach denies that any of the mammalia have the rugæ transverse, except the *monkey* and the *mare*. He seems to have mistaken the folds of the vulva in the *mare* for the rugæ of the vagina.

In the *whales*, the vagina is described by Hunter as being smooth upon the internal surface for the first half of its length, and afterwards valvular. He states the number of these valves to be from six to nine; to be directed outwards, and each of them to resemble an *os tinæ*. At first they do not go quite round, but afterwards make complete circles.

The *hyæna* has also transverse rugæ in the first half of the vagina.

The vulva and vagina seem to be confounded with each other

MAMMALIA.

other in the *tardigrada*, and in the *edentata*, the canal which conducts to the uterus in these orders being extremely short.

The *uterus*, in a few tribes of mammalia, possesses the same triangular form as in the human subject; such is the case in the *tardigrade* quadrupeds, the *ant-eaters*, the *pangolins*, and the *armadillos*. It is nearly similar in the *monkey* kind, but in these the body is more round, and the neck is distinguished from the rest of the uterus by a contraction.

In all the remaining orders of mammalia, except the *marsupial* animals, the body of the uterus is more or less prolonged on each side, and forms what have been called *cornua*. The extent of these lateral divisions is, in many instances, very considerable; they often reach into the loins, in which cases the *broad ligaments* of the uterus are much spread out, and in the large quadrupeds there are muscular fibres placed between their laminae. According to Cuvier these form different fasciculi in the *cow*, one of the strongest of which extends from the ovary to the neck of the uterus. It approximates these parts, but for what purpose is not known. Besides these there are some transverse fibres, which go from one horn of the uterus to the other, in the first third of their length. The round ligaments also possess, in general, muscular fibres. The division into cornua is less marked in the *lemurs* than any other genus. They have the uterus rather formed into two lobes than cornua.

The neck of the uterus is very short in some species; in the *agouti*, the *paca*, and the *guinea-pig*, it can scarcely be said to exist, and in the *hare* and *rabbit* there is no part corresponding to the neck, but the two branches or cornua of the uterus open immediately by two distinct orifices into the vagina.

In the *ornithorhynchus* and *echidna* there is no neck or body, properly speaking, to the uterus. The organ consists merely of two large convoluted tubes, which terminate by two distinct orifices in a common canal, which leads from the bladder to the cloaca, and appears to serve also the purpose of the vagina. The first portion of these tubes is the widest. This corresponds apparently to the cornua uteri. The succeeding part is the most contracted; but terminates in a wide mouth that seems to supply the place of the Fallopian tube, which is wanting in these animals.

The plan on which the uterus is formed in the *marsupial* animals is very peculiar. There are parts corresponding to the cornua, and to the body of the uterus, and in addition to these, two lateral canals. The cornua are oval cavities continued into small canals that extend to the ovaries, and are the Fallopian tubes. The oval cavities have been generally considered as the dilatations of these tubes, but Cuvier asserts that they are very distinct from the small parts of the canal which are really the Fallopian tubes. The openings of the cornua into the part corresponding to the body of the uterus are separate from each other, and are guarded by valvular folds. The body of the uterus is a straight canal, which is widest at the fundus, or the part that receives the horns, and becomes gradually less capacious as it approaches its termination, which is in the vagina, close to the orifice of the urethra. The body of the uterus is a single cavity in the *kangaroo*, *phascolumys*, and the *phalanger*; but in the *Virginian opossum*, the *wombat*, and *koala*, the uterus is double, or consists of two cavities. Mr. Bell has described these in the *wombat* as having a pyramidal form. The right was considerably the largest, being about the size of a pullet's egg. It should be observed, however, in this instance, that the right uterus was gravid. From the fundus of each of these uteri there was a Fallopian tube, nearly three

inches long, which terminated at the ovarium. This tube had no dilatation at its junction with the uterus, which appears to confirm Cuvier's opinion of the dilatations in the *kangaroo*, &c. answering the purposes of the cornua uteri. The double uterus of the *wombat* had a common neck half an inch long, and of considerable breadth and thickness, which however had two orifices in the vagina. In the *Virginian opossum*, the two cavities of the uterus are formed by a longitudinal septum of the part corresponding to the body, and each of these cavities has a separate opening into the vagina. In the *kangaroo*, *phascolumys*, and *phalanger*, there is but one opening from the uterus into the vagina, which is stated by Mr. Home to be so small in the virgin *kangaroo* as to be scarcely discernible.

By comparing the number and situation of the communications of the uteri in the vagina, with the form of the male organs in the *marsupial* mammalia, it will be sufficiently plain that the semen passes, as in other cases, into the uteri directly, and not by the circuitous course of the lateral canals, as some have supposed.

The *lateral canals* arise in the *kangaroo* from the fundus of the body of the uterus where the cornua terminate, and in the *wombat* from the posterior surface of the common neck of the two uteri, near its junction to those uteri. The canals describe a femicircular curve, and terminate in the vagina, on each side of the orifice or orifices of the uterus.

The use of these lateral canals it is difficult to explain. It has been observed, that the ovum of the *marsupial* animals had no connection with the parietes of the uterus, but were involved in a species of jelly, which has been supposed to supply the nourishment of the fœtus. Mr. Home has conjectured that the jelly is secreted by the lateral canals, because they become shut towards the vagina, enlarged throughout, and maintain a free communication with the uterus after impregnation. We are not, however, sufficiently acquainted with the history of gestation in these animals, to determine whether the changes in the canals subsequent to impregnation, may not be required for other purposes than the secretion of the jelly found in the uterus.

The uterus has but rarely, in mammalia, that projection around its orifice which is called the *ostium* in the human subject. Most commonly the os uteri is a transverse slit at the end of the vagina, and so much on the lower part of that canal, that the superior parietes form a cell or cul-de-sac above it. In the *porcupine* the os uteri has so slight a prominence, that it appears as an opening of the inferior part of the vagina. In the *bear*, *cow*, and others, the vagina makes a projection which tends to obstruct the passage into the uterus.

The *structure* of the uterus is the same in the *monkey* and the human subject; but in the other mammalia the parietes are thin, and generally composed of layers of red muscle, superadded to the internal membrane, and external coat in the same manner as the alimentary canal is formed. These muscles are particularly plain in the double uterus of the large quadrupeds. There is a transverse layer of muscle upon the cornua covered by a thin layer of longitudinal fibres. The neck of the uterus has commonly the transverse layer only. The principal thickness of the neck of the organ in the *cow* is, however, composed of a white hard texture, resembling the substance of the human uterus.

The internal membrane of the body of the single uterus, and of the cornua of the double uterus, usually exhibits longitudinal folds, but in the *civet* they are transverse, and inserted into each other.

The changes of structure which the uterus undergoes after impreg-

MAMMALIA.

impregnation will be described under the head of OVUM, *History of, in viviparous animals*, in the subsequent part of this dictionary.

The uses of these changes will be more easily understood, by being contemplated in conjunction with the parts immediately connected with the embryo. We shall also reserve the account of the *mamma*, and *marfupia*, or *suckling pouches*, for the same head, as these organs are likewise subservient to the dependent state of existence of the young animal.

In *Plate IX.* of the *Anatomy of Mammalia*, the structure of the unimpregnated female organs is exemplified. *Fig. 1.* represents the uterus, vagina, and vulva of the *bear*, a portion of the parietes of the two latter parts being removed, to expose their internal surface: *a* is the mouth of the vulva; *b* is the clitoris, half concealed in its prepuce pouch; *c*, the internal surface of the vulva; *d*, the valvular fold corresponding to the hymen, under which the orifice of the vagina is seen; *e*, the vagina laid open; it is shorter than the vulva, and its longitudinal folds are crossed by grooves; *f*, the crucial slit that leads to the uterus; *g*, the body of the uterus; *h, h*, the two cornua. *Fig. 2.* shews the double uterus of the *rabbit*: *a* is the *vulva* opened; *b* is the clitoris; *c*, the vagina laid open; *d, d*, the orifices of the two uteri or cornua in the vagina. *Fig. 3.* exhibits the female organs of the *ornithorhynchus paradoxus*: *a*, the *cloaca* laid open; *b*, the vagina, or canal which receives the urine, and the two lateral tubes or oviducts; *c*, the opening into the bladder; *d, d*, the two orifices of the oviducts; *e, e*, the dilated parts of the ducts, which apparently correspond to the cornua uteri; *f, f*, the contracted portions of the ducts which represent the Fallopian tubes; *g, g*, the termination of the ducts, which probably supply the place of the infundibula of the Fallopian tubes. *Fig. 4.* is a view of the female parts in the *kangaroo*: *a* is the short canal corresponding to the vulva and vagina laid open; *b* is the clitoris; *c*, the meatus urinarius; *d, d*, the lateral canals arising at the fundus of the body of the uterus, and terminating in the vagina; *e*, the middle canal which corresponds to the body of the uterus in other mammalia; *f, f*, the dilated parts which Mr. Home has considered as belonging to the Fallopian tubes; but which Cuvier, more correctly, in our opinion, calls the cornua of the uterus; *g, g*, the parts of the tubes which really represent the Fallopian; *h, h*, the ovaries; *i, i*, the ureters.

If we except the formation of the tubes which correspond to the Fallopian in the *marfupial* mammalia and the *ornithorhynchus*, and the *echidna*, there is scarcely any peculiarity to be remarked in the Fallopian tubes in mammalia. Blumenbach states that they are found to be convoluted, sometimes so as to form a knob, as in the *pygmy (Simia sylvanus)*, and in the *opossum*. The fimbriated extremity of the tube is constructed like a funnel in the *rabbit*, &c.

The ovaries of mammalia possess the same structure, as to all material circumstances, with those in the human subject. The figure of these bodies is frequently more round in their shape than in woman. In general, the vesicles containing the ova are buried in the substance of the ovaries, as in those of the human species; but in some quadrupeds they are found near the surface, so that the ovaries appear tuberculated: this has been observed in the *pig*, the *civet*, and in the *opossum*, the ovary of which last is entirely made up of the vesicles. The most unusual form of the ovary is in the *hedge-hog*. The *vesicula Graafiana* are contained in capsules, which are distinct externally, but connected together by their foot-stalks, somewhat like the *racemus vitellorum* of birds.

The *corpora lutea* grow much larger than the cells of the ovary from which the vesicles have been expelled, at least

in some quadrupeds. We have observed them, in the *sheep*, to be composed of a solid, firm, fleshy substance, intersected by membranous lines, somewhat like a carcinomatous tumour, and to be about the size of a small cherry.

Fig. 5. *Plate IX.* of the *Anatomy of Mammalia*, exhibits the ovary of the *hedge-hog*, which appears like a cluster of ova bound together. *Fig. 6.* represents a portion of the ovary of the *sheep*, from which an ovum had been recently discharged: *a* is the vacant cell. *Fig. 7.* is another portion of the ovary of a *sheep*, in which the deposit above described had been made in a cell, after the ovum had left it: *a* is the section of the substance of the ovary; *b* is the section of the new substance, or, as it is called in other cases, the *corpus luteum*.

Bones.—The skeletons of mammalia exhibit many important peculiarities, not only as compared with that of the human subject, but with each other. This class has great varieties in the modes of locomotion; and consequently in the organs by which these are effected. In all the deviations in the mechanism of the skeleton, the *quadrumanous* tribe seems to be the model. Thus, the parts which constitute the arm and hand, or are necessary to make a prehensile member, are found in those that employ the extremities for walking, flying, or swimming, in a greater or less degree obliterated, changed, or concealed; although the members have so different a form externally. The long tail also seems to be the model from which the short coccyx of some mammalia and of man is the deviation.

The interior composition of the bones of mammalia is generally the same as in man. Their texture is most close and dense in the small quadrupeds. We have observed the bones to be particularly hard and fragile in the *kangaroo*, but this might have been from the manner in which they had been prepared. The bones of the *cetacea* exhibit very plainly the fibrous structure, it being more loosely arranged than in the *terrestrial* mammalia. In the long bones, the osseous fibres can be easily separated, and the cells of the spongy bones are exceedingly evident. Both in the *seals* and the *cetacea*, there are no large medullary cavities in any of the bones. The texture of the bones in these animals has the effect of rendering them lighter than those of other mammalia; and therefore better suited to locomotion in the water. The vertebrae of the *whale* tribe, especially those towards the end of the tail, are much more dense in their structure than the other bones. All the cells of the bones in those animals are filled with fluid oil.

It has been attempted to establish a regular gradation in the proportions of the magnitude of the cranium to that of the face amongst the different mammalia, with the view of fixing the relative size of the brain, and consequently the degree of intelligence possessed by the animal.

Daubenton and Camper proposed measuring the relative size of the cranium, by supposing two straight intersecting lines to be drawn upon the cranium and face. The angles which they exhibit in different species determine the relative bulk of these parts. Camper's method was the most accurate. He drew one line upwards, which touched the incisor teeth of the upper jaw below, and the greatest projection of the forehead above; this he called the *facial line*. The other line was supposed to pass along the lowest part of the cranium. It was taken in the plane corresponding to the external meatus auditorius and the floor of the nostrils, and was called the *basilar line*. The angle formed between these two lines determines, according to Camper, the differences of the crania of animals, as well as the national physiognomy of the various races of mankind.

M A M M A L I A.

It is obvious, however, that the projection of the frontal sinuses in many of the large quadrupeds, especially the *elephant*, must, in a degree, interfere with the accuracy of this mode of measurement. The great size of the nasal cavity in some species, and the prolongation of the jaws in others, will also form exceptions to a rule founded upon this principle of measurement. Blumenbach states that about three-fourths of all the species of quadrupeds with which we are acquainted, whose crania differ extremely in other respects, have the same facial line.

Nevertheless it must be admitted, that the proportions which the cranium (as indicating the bulk of the brain) bears to the face, serve in general to determine the mental endowment of animals. It is strikingly proved by the *monkey* tribe, which most nearly approach the human subject in the form of the head, possessing so much more of the mental character of man than any other animal in the class.

The following table will shew the number of degrees of the facial angle in several species of mammalia.

<i>Young ourang-outang</i>	-	-	-	67°
<i>Sapajous, or prehensile-tailed monkeys</i>	-	-	-	65
<i>Talapoin monkey</i>	-	-	-	57
<i>Young mandril</i>	-	-	-	42
<i>Coati</i>	-	-	-	28
<i>Pole cat</i>	-	-	-	31
<i>Pug dog</i>	-	-	-	35
<i>Mastiff dog, the tangent taken at the external surface of the cranium</i>	-	-	-	41
<i>Ditto, at the internal surface</i>	-	-	-	
<i>Hyæna, at the external surface</i>	-	-	-	40
<i>Ditto, at the internal</i>	-	-	-	25
<i>Leopard, at the internal surface: a tangent cannot be drawn to the external surface, on account of the convexity of the nose</i>	-	-	-	28
<i>Hare</i>	-	-	-	
<i>Marmot</i>	-	-	-	25
<i>Porcupine</i>	-	-	-	23

These three last are measured by the internal surface of the cranium, it not being possible to bring a tangent to the external.

<i>Pangolin</i>	-	-	-	39°
<i>Barbirouffa</i>	-	-	-	29
<i>Ram</i>	-	-	-	30
<i>Horse</i>	-	-	-	23
<i>Dolphin</i>	-	-	-	25

According to this table, the facial angle of the *ourang-outang* does not differ materially from the human, the adult *negro* having it only 70°. In the *European head* it is 85°, a difference generally considered as accompanying a gradation of the intellectual powers in these races of mankind. This opinion is not a modern one, but seemed to have been entertained by the ancients, who always made the cranium, in the statues of their gods and heroes, project more than is observed in any human head. The facial angle of many of the antique statues is 100°.

Another method of arriving at the relative bulk of the cranium and face, is to measure and compare the area of each, after there has been a vertical and longitudinal section made of them. The area of the section of the *European human cranium* is four times as large as that of the face; the lower jaw not being included. In the *negro*, the cranium remaining the same, the area of the face is increased about $\frac{1}{5}$ th. In the *Calcutta* only $\frac{1}{6}$ th. In the *ourang-outang* the propor-

tion of the face is further increased. It is nearly equal to the half of the cranium, in the other *monkeys* and the *digitigrade quadrupeds*.

In the other orders, the area of the face is generally larger than the cranium. The *hare* and *marmot* have it $\frac{1}{3}$ d larger. It is nearly twice as large in the *cloven-footed quadrupeds*; still more than double the size in the *porcupine*; nearly three times in the *hippopotamus*, and almost four times the size in the *horse*.

The *cetacea* have the face so much flattened, in consequence of wanting the nasal cavity, that it does not admit of a fair comparison with the cranium.

These modes of measuring the cranium only indicate the extent of its circumference in one direction. In order to arrive at the real bulk of the cranium, or of its contents, it would be necessary to make a vertical section from one side to the other, and a transverse section, so as to detach the upper half of the skull from the lower, as is done for the dissection of the brain; or, what would be still more satisfactory, to weigh the brain, first having ascertained the variations in the weight of a given bulk of brain in different species, if any do exist.

The number of bones composing the cranium in mammalia is frequently different from what is found in man. In some species certain bones remain during life in separate pieces, while in others, the sutures that are always found in the human cranium are so early obliterated, that two, three, or more bones are consolidated into one.

The *quadrumanous*, and all the *hoofed mammalia*, have frequently the sphenoid bone in two parts. The suture of the middle of the os frontis is found in the *digitigrada, saltigrada, the hog, tapir, hippopotamus, rhinoceros, seal, and morse*. In the *cloven and solid-footed quadrupeds* it exists for a considerable time. The bone containing the cavity of the tympanum is divided by a suture from the rest of the temporal bone in the *cat, dog, and civet* genera; the *saltigrada, the ruminants, solipeda, seal, lamantins, and cetacea*.

The ossa parietalia are united into one bone in the *chiroptera, digitigrada, hare, cavy, porcupine, marmot, rat, and squirrel*; the *hog, tapir, hippopotamus, rhinoceros, the ruminants, the solipeda, and lamantin*.

In the *cetacea* the parietal, occipital, and temporal bones are united together; although the sphenoid is long, distinct, and even divided into several pieces.

All the sutures of the cranium are very soon obliterated in the *elephant*.

The bones of the cranium in mammalia have not always the same connections with each other as in man. Even the *ourang-outang*, whose head bears so strong a resemblance to the human, does not agree in this respect. This animal, as well as many other species of *monkey*, has the temporal wing of the os sphenoides very narrow, and not extended to the parietal bone: the temporal bone is partially joined to the frontal. The *jocko* has the temporal bone articulating by its squamous portion immediately with the os frontis, the temporal ala of the sphenoides not being connected with either the frontal or parietal bones. In the *sapajous, or monkeys with long prehensile tails*, the parietal bone is articulated with the os maxilla. In the *howling baboons*, and the *digitigrade quadrupeds*, the bones of the cranium have the same connections as in man.

In all the *saltigrada, the armadillos, pangolins, and sloths*, the sphenoid does not articulate with the parietal bone; but in the *ant-eater* these two bones are extensively connected.

In the *ruminants* the os sphenoides has the same connections

MAMMALIA.

as in man, but in many of the *many-hoofed* quadrupeds the sphenoides is not joined with the parietalia.

The *futures* of the cranium of mammalia, in general, are apparently less marked than in man. Their denticulations are, however, very plain in the *ruminating* quadrupeds. The *ossa triquetra* are not often met with. Blumenbach reports that he possesses specimens of them in the *ourang-outang* and the *bare*. All the *futures* in the *cetacea* are squamous.

There are considerable varieties in the form of the different bones of the cranium. In the *ourang-outang* the *os frontis* has a more irregular outline than in man; its processes are more eminent, and the orbital arches are more elevated. This bone is triangular in the *monkeys*, with long prehensile tails; but in the other species of *simia* it is oval, and the arches of the orbits are flattened superiorly, and prominent. The orbits of the *monkey* tribe, although opening anteriorly like the human, are much closer together.

The orbits are first observed to incline outwards in the *lemurs*.

In many of the quadrupeds which have the orbits directed to each side, the *os frontis* has a square figure.

The *saltigrada* and the *hog*, however, have a notch or vacancy in the orbital arch, which gives, in a degree, a rectangular figure to their frontal bones. The orbits of the *beaver* look upwards. In the *digitigrada*, the *cloven* and *solid-footed* quadrupeds, the orbital arch has also a deficiency at the posterior part.

The frontal bone forms a vault over the orbits in the *hippopotamus*, the *ruminants*, and the *horse*.

In the *mole*, *ant-eaters*, and *cetacea*, the orbits are so shallow, that they can hardly be said to exist. There are also no orbital arches, properly speaking, in the *hedge-hog*, *shrew*, *seal*, *horse*, or *rhinoceros*. In the *cetacea* the frontal bone is narrow from before backwards; the processes corresponding to the orbital descend below the maxillary bone.

The *parietal* bones of the *ourang-outang* have the inferior anterior angle very prominent, on account of the small extent of the squamous portion of the *os temporis*. It is the same, or more so, in the other *monkeys*.

This angle of the parietal is still more prolonged in the *lemurs*. It is very broad and much extended in the *ant-eater*, the *squirrel*, &c.

There is a separate piece of bone sometimes found in the *saltigrade* mammalia, between the parietal and occipital bone. It has been described in the *common mouse* by Meyer, under the name of the *os transversum*.

The single parietal bone of the *ruminants* has the occipital crest before it in the *antelope bubalis*, and resembles a ribbon surrounding the back part of the head.

The *occipital bone* departs more from the form and position it has in the human head, than any other bone of the cranium.

The occipital ridge or crest is not more marked in the *ourang-outang* than in the human subject; but in the other *monkeys*, especially those with elongated jaws, the *os occipitis* begins to form the angle at the crest, which is so striking in most quadrupeds. The transverse occipital ridge is very prominent in the carnivorous quadrupeds, whether *digitigrade* or *plantigrade*, making the upper part of the occiput angular, and beneath this the cranium flat or concave. The longitudinal occipital ridge is very strong in the *badger*.

The *ruminating* quadrupeds, likewise, have a very projecting occipital ridge, and the *beavers* are remarkably so. In the *pig* the occiput has the figure at the upper and back part of a very acute angle.

The occiput is round in the *ant-eater* and *cetacea*; it is smooth and without processes in the *mole*.

The *elephant* has the occiput nearly square, and the condyles at the posterior extremity. There is no occipital protuberance, but a depression in place of it, containing a longitudinal ridge for the insertion of the ligamentum nuchæ.

The *mastoid process* belongs to the occipital bone in all mammalia, except the *monkey*, in which it is an appendix of the *os temporis*, as in man. This process in the *apes*, and most of the *monkey* kind, is nearly obliterated. Most of the *digitated* quadrupeds want the mastoid process, and merely have a slight protuberance from the projecting part of the cavity of the tympanum; or this cavity itself supplies the place of the mastoid process. The *cavy*, *hog*, *guinea-pig*, the *cloven* and *solid-footed* quadrupeds, &c. have a long mastoid process behind the cavity of the tympanum.

The position of the *foramen magnum* is remarkably different from that of the human subject; it removes from the under part of the head, even in the *monkey* tribe, and in the true quadrupeds is found at the posterior part of the cranium, and situated so, that the edge, which is posterior in man, is directed obliquely upwards. This edge is in some quadrupeds turned directly upwards, or, as in the *alpine marmot*, is even turned more forwards than the other edge of the hole. The relative position of the occipital foramen was employed by Daubenton to determine the gradations of the crania of different animals. He drew one line from the edge of the hole, which is posterior in man, but superior in most quadrupeds, as already mentioned, through the lower edge of the orbit; another line was taken in the direction of the foramen itself, beginning at its posterior edge and touching the articular surface of the condyles. The angle formed by the intersection of these two lines, was considered by Daubenton as indicating the variations of form and magnitude of different crania. It has been objected to by Blumenbach, upon the same ground that he disapproved the facial angle of Camper, namely, its not expressing all the variations that exist.

The *squamous* portion of the *temporal* bone, as already noticed, is much less extensive in mammalia, even in the *ourang-outang*, than in man. The principal part of this bone, as it appears externally in many quadrupeds, is the zygomatic process. The petrous portion of the *os temporis* will be described along with the other parts of the organ of hearing, to which it properly belongs.

The *zygoma* is not merely formed by the junction of the processes of the temporal and malar bones, but has an intermediate piece of bone in the *otter*, *opossum*, *beaver*, *guinea-pig*, &c. Cuvier also mentions a particular bone which supplies the place of the zygomatic angle of the *os maxillæ* in the *green ape*, but which bone is soon ankylosed with other malar.

The *zygoma* is remarkably broad in the *opossums* and the *kangaroo*.

In the *mole*, it is a straight process, not much thicker than a needle.

In the *cetacea*, at least the genus *delphinus*, the *zygoma* is a very slender osseous bar.

In proportion to the extent and strength of the masseter muscle, the *zygoma* forms a curvature in an upward direction, and when this muscle is less considerable, the *zygoma* is either horizontal, or makes a convexity downwards. The *zygoma* is universally arched upwards in the *carnivorous* quadrupeds. The *saltigrada* have the convexity downwards, and in the *cavy* and the *paca*, it even extends below the distance of the molar teeth.

M A M M A L I A.

The zygoma of the *fus æthiopicus* is nearly horizontal, but is extremely broad and thick, and forms all the broad-part of the cheek under and before the eyes.

The curvature of the zygoma outwards, which gives it properly the name of an arch, depends upon the magnitude of the temporal muscle which passes under it. We, therefore, find the zygomatic arch very wide in all the *carnivorous* tribe of quadrupeds, and particularly so in the *cat* genus, upon which depends the round shape of the head of the *tiger*, *leopard*, *cat*, &c. in a great measure.

The large *herbivorous* quadrupeds, in general, have the zygoma but little arched outwards. It is the same in most of the *saltigrada*.

The zygoma is quite straight in the *mole*, and in the *cetacea*.

It is not found to form an arch outwards, of any consequence, in the *edentata*. In the *Cape ant-eater* it is perfectly straight.

In the *pangolins* and *American ant-eaters*, the zygomatic arch is incomplete; the latter animals have merely two tubercles in place of the processes, which usually form the zygoma.

The zygomatic arch, also, is not complete in the *sloths*. The os male terminates posteriorly in two angles; the one superior, which extends above the zygomatic process from the os temporis; the other inferior, which passes obliquely downwards, and is unattached.

We shall describe the *ethmoid bone*, more particularly, under the head of the organ of smelling, by which its uses will be more apparent.

The large *fossæ*, or depressions upon the inner surface of the base of the cranium, are shallow in proportion as the animal is removed from man.

Even the *howling-baboons* have the posterior and intermediate fossæ, and the *fella turcica*, in the same plane.

Many quadrupeds want the *fella turcica*, as the *digitigrada*, and most of the *saltigrada*. In the *cavy*, the *rhinoceros*, and the *clowen-footed* quadrupeds, the part having the situation of the *fella turcica* is even depressed, instead of being elevated.

Some of the spinous ridges on the internal part of the cranium, are often more eminent in mammalia than in man.

In the greater number of the *carnivorous* species, there is a thin projection of bone from the petrous portion of the os temporis, which strengthens the tentorium of the cerebellum. It is usual to say that these animals have a bony tentorium, and to suppose that it is necessary to defend their brain from concussion, during the rapidity of their motions, which does not seem probable, as something of the same structure is found in other species whose movements are slow.

The limits between the middle and posterior fossa of the cranium is formed in the *pangolin* by a large vertical osseous septum, with an oval hole in the middle.

In the *rhinoceros*, the part corresponding to the posterior clinoid processes is not attached to the base of the cranium; but extends like a bridge from one middle fossa to another, while the depression that is in place of the *fella turcica* communicates under this bridge with the cuneiform process of the occipital bone.

The *foramina* upon the inside of the cranium are often less distinct, and consequently less numerous in mammalia than in man.

The *optic foramina* are close together in the *agouti*, being only separated by a thin osseous plate. They are united into one hole next the scull in the *bare*, the *four-toed ant-*

eater, and the *elephant*. The *chevrotin (moschus)* has but a single optic foramen, which is divided by the vomer.

The *spheno*, or *superior orbital fissure* in the *curang-outang*, is similar to that of the human subject; but in almost all the other mammalia it is nearly a round hole. In many of the *saltigrada*, and the *rhinoceros*, *elephant*, and *hippopotamus*, it is incorporated with the foramen rotundum. They are also confounded in the *clowen* and *solid-footed* quadrupeds.

The *foramen rotundum* in the *monkey* is marked with a furrow for some way before it leaves the cranium. This hole is very large, and more of an oval than a round shape in the *digitigrade* quadrupeds.

The *foramen ovale* of the *bear*, *cat*, *civet*, &c. is defended at the external edge by an osseous lamina.

The *bear*, *badger*, *seal*, and *vampyre bat*, have this foramen united into one with the foramen rotundum.

The foramen ovale is thrown into one with the *anterior foramen lacerum* in the *cavy* and *porcupine*. In the *ten-banded armadillo*, and the *four-toed ant-eater*, it is confounded either with the foramina lacera, which are united, or with the foramen rotundum, which is thus rendered very large, and of an oblong form. It is conjoined with the anterior foramen lacerum in the *elephant* and *hippopotamus*. It is very large in the *ruminating* quadrupeds, and does not exit as a separate hole in the *solipeda*.

The *foramen lacerum anterius* is not found in the *monkey* kind, the *digitigrade*, the *squirrel*, and the *ruminating* quadrupeds.

It is very wide in several of the *saltigrada*. It is confounded with the *posterior foramen lacerum* in the *armadillo*, the *hippopotamus*, and *solipeda*.

The *canalis carotidæus* is much shorter and less tortuous in the *digitigrada* than in man. There is no canal in the *saltigrada*; the carotid passing immediately through the foramen lacerum. In the *hippopotamus* the carotid canals are lost in the foramina lacera.

The *foramen lacerum posterius* is a very small round hole in the *pangolin* and *sloth*; and in the *elephant* it is very large. In the two first of these animals the anterior condyloid foramen is remarkably large; and in the last there is no hole before the condyles, which shews the connection that exists between these two foramina.

The foramen lacerum posterius is confounded with the anterius in the *rhinoceros*; and the *anterior condyloid hole* is very large. There are sometimes two condyloid foramina on one side, which are united into one.

The two tables of the cranium are in general less distinct in mammalia than in man, or appear to be more perfectly ossified; but in the *elephant*, the magnitude of the cranium depends in a great measure upon the separation of the two tables, between which are interposed a number of large cells of a very irregular figure, which are filled with air instead of medullary substance, and communicate with the Eustachian tube, and by that means with the external air. The cellular structure of the cranium in the *elephant* is similar to that found in the head of the *owl*, and designed in both to produce an increase of bulk, without an additional weight.

The *bones of the face* differ very much in this class, both in their forms and connections, from those of man, in consequence of the great prolongation of the jaws, and the lateral position of the eyes, in most mammalia.

The form of the upper jaw arises in a great degree from the presence of two bones, which are placed between the two ossa maxillaria. These have received different names, such as *intermaxillary* or *labial bones*; or frequently they are called the *os incisivum*, from the circumstance of their holding the incisor teeth, when they exist: they are called also *os*

MAMMALIA.

palati by Blair, and *os maxillaire interieur* by Vitel. The intermaxillary bones have been considered by some anatomists as forming a distinction between all mammalia and man; but they have not been found in several species of *monkey*; and Fischer, who wrote a treatise on this subject, states that he did not find an intermaxillary bone in the *three-toed sloth*, and in the *horse-shoe bat*; but he admits that the bone might have been broken off, at least in the *sloth*. Cuvier says that the *sloths* have very small intermaxillary bones. Vic d'Azir has ascribed these bones to the human subject, considering the small transverse fissure, seen within the incisor teeth of the human fœtus, as the future connecting the intermaxillary bones or bone with the upper jaw; but all other anatomists deny the intermaxillary bones to man.

These bones vary much in different species, with respect to form and size. They are small in some of the *digitigrade quadrupeds*, in the *rhinoceros*, and in the *walrus*; although Cuvier states them to be large in the *lamantin*. They are particularly large in the *saltigrada*, in which they make the whole front of the upper jaw, and contain the large upper gnawing teeth of these animals. They are large also in the *elephant*, *hippopotamus*, *porpoise*, and *physeter macrocephalus*. In the *ornithorhynchus* these bones exist, although there are no incisor teeth; and the form of the jaws is so very peculiar, resembling in this animal the bill of a duck. The intermaxillary bones consist of two hook-shaped pieces, united by a broad cartilage.

The *proper maxillary* bones contain still in mammalia the posterior teeth of the upper jaw. These bones contribute more than any other to the composition of the face: even in the *monkey* tribe they begin to be prolonged, and assume something of the figure they possess in the true quadrupeds.

In the *cheiropteros*, *digitigrade*, *plantigrade*, and *pedimanous* mammalia, the nasal processes of the maxillary bones become so broad as to separate the orbits sufficiently, to give them a lateral position. The *saltigrada* have these bones carried so far back by the great size of the intermaxillary bones, that they form a considerable portion of the orbit, the palatine bones having but little concern in the composition of it.

The maxillary bones of the *sloths* also extend to the orbits.

In the *ant-eaters* these bones are very long and narrow, resembling a portion of a cylinder; but they do not contribute to the formation of the orbits.

The maxillary bones of the *tapir* pass backwards, and make the floor of the orbits: they also extend to the orbit in the *rhinoceros*.

In the *hippopotamus* these bones have no share in the orbit; they are very strong inferiorly, in order to accommodate the superior tusks, which are placed in them, and not the intermaxillary bones.

The *daman* has the inferior surface of the orbit formed by the superior maxilla: it makes a small part of it on the *ruminants*.

In the *lamantin* the maxillary bones constitute the base of the orbit, and afterwards extend a considerable way behind it.

In the *cetacea* they are much elongated, and reach to the very end of the flattened snout of these animals: they ascend upon the side of the blow-hole, and cover that part of the *os frontis* which forms the arch of the orbit.

The *malar bone*, in a great number of mammalia, is less in proportion than it is in man, and does not articulate with either the orbital process of the *os frontis* or the sphenoides, but merely forms a part of the zygoma and the lower margin

of the orbit. In these cases, the frame of the orbit is incomplete at the posterior part, and communicates with the fossa for lodging the temporal muscle. It is thus with the *cheiroptera*, *digitigrada*, *plantigrada*, *saltigrada*, *pedimana*, *edentata*, and *multungulata*. In the *saltigrada* the *os malæ* is placed in the middle of the zygoma; the superior maxilla supplying the anterior zygomatic process, in place of the malar. The temporal fossa is completely thrown into one cavity, in the *rhinoceros* and *elephant*.

The frame of the orbit is completed externally by the union of the malar and frontal bones; but there is an opening behind this from the orbit into the temporal fossa.

In the *solipeda* the malar and frontal bones unite by a process of the latter, which descends on the outside of the orbit, and furnishes the margin of this cavity; but it is open behind into the temporal fossa, as in the *ruminants*.

The *nasal bones* are commonly prolonged, in proportion to the other parts of the face in mammalia. In some of the *monkey* tribe they are united into one bone, which is very narrow. In the *long-prehensile-tailed monkeys* the interspace between the orbits is very narrow, and posteriorly merely forms a septum.

These bones are longest in the true quadrupeds, and most so in the *saltigrada*, whose external nares open immediately above the incisor teeth.

In the *hog*, the *tapir*, *hippopotamus*, and the *rhinoceros*, the nasal bones are not conjoined with the jaw at their anterior extremity, but form a distinct process, which stands out above the intermaxillary bone. This process sustains the process of the *tapir* and *hog*, and the horn of the *rhinoceros*, or the anterior one when there are two, as in the *bicornis*.

The process which supports the trunk of the *elephant* is still more unlike the common nasal bones.

The nasal bones of *cetacea* are two small tubercles implanted in the *os frontis*.

The *lacrimal bone* is sometimes wanting, as in the *elephant*: in other instances it is remarkably large, in the *anteater*, the *opossum*, the *ruminating quadrupeds*, especially the *antelope*. It advances a little upon the cheek in the *flying lemur*.

According to Cuvier, the *ethmoid bone* has no share in forming the orbit in the *cheiroptera*, *digitigrada*, *plantigrada*, and *pedimana*: its place is supplied by the orbital process of the *palatine bones*, which are very large in these animals.

The *palatine bones* also constitute, in the *long-nosed edentata*, the lower part of the surface of the depression corresponding to the orbit. The *pterygoid processes* also are produced by two laminae, which are continued with the *ossa palati*, and which, having joined each other inferiorly, prolong the canal of the nares to the foramen magnum of the occiput.

In the above description of the bones of the upper portion of the face, we have anticipated most of the circumstances respecting the *nasal* and *orbital fossæ*.

It should be mentioned, that the *hog* has two small peculiar bones, situated between the point of the *ossa nasi* and the corresponding intermaxillary bones. These serve to strengthen the snout, and are therefore called by Cuvier the *bones of the snout*.

The *nasal fossæ*, although always opening nearer the front in quadrupeds than in man, are liable to vary with respect to their situation. In the *saltigrada* the external nares are quite at the end of the snout, as already mentioned. In the *elephant*, the nasal fossæ are at about an equal distance from the top of the cranium and the edge of the alveoli. In the *seal*, they are directed upwards. They are far forwards in the *morfe*. In the *cetacea*, the openings into the blow-hole, which

MAMMALIA.

which correspond with the nasal fossæ, are immediately before the os frontis, and open upwards and backwards.

We have already mentioned the figure of the margin of the orbit in several species. In the *cetacea* there is a fossa corresponding to the orbit, although the eye of these animals is surrounded only by the soft parts. This fossa has a semi-circular roof, formed by the os frontis; but it is quite open below, down to the lower jaw.

The *spheno-maxillary fissure* is shorter in all the *monkey* tribe than in man: it is contracted to the shape of a hole in the *long-prehensile-tailed monkeys*, and is closed altogether in the *howling baboon*. In the other mammalia, which have the orbital and temporal fossæ united, it does not exist.

The *sub-orbital foramen* is single in most mammalia, as in man; but in some there are two, or three, or more holes under the orbit; in which cases they are small. There are, according to Cuvier, two in the *ourang-outang* and the *prehensile-tailed monkeys*, three in the *common monkeys* and *Barbary ape*, four or five in the *ribbed-nosed ape* and *hair-lipped ape*. There are three or four holes in the *cetacea*. From the position of the orbits in these animals being so low, the maxillary bones are above them, and contain the holes corresponding to the sub-orbital.

The sub-orbital foramina are large in most of the *whiskered* quadrupeds, for the transmission of the great nerves that are distributed to those parts. In the *cavy*, *agouti*, *porcupine*, and many of the *rat* tribe, they are prodigiously wide; and in the *jerboa*, nearly equal in size the orbits themselves.

The greatest deviation from the human subject, with respect to the foramina of the face, is to be observed in the *foramen incisivum*. This hole is small and single in the *ourang-outang* and *chimpanzee*, but enlarges a little in the other species of *simia*. There are two foramina very distinct from each other in almost all the other mammalia: they are remarkably large in the *saligrada* and *clawed-hoofed* quadrupeds; in the *bare* they even exceed the extent of the solid part of the palate.

It is single and large in the *tapir*, *rhinoceros*, *horse*, and *lamantin*; it is nearly obliterated in the *mongoose*; small and far from the alveolar process of the jaw in the *dugong*; and wanting altogether in the *cetacea*.

Peculiarities of the *lower jaw* are to be found in its composition, general form, direction of its ascending ramus, and the figure and relation of the condyloid and coronoid processes.

The inferior maxilla remains, during life, in two pieces, united by cartilage or ligament at the front, in most mammalia. These are ankylosed together, as in man, at an early period, in the *monkey* kind, the *vampire*, and several other *bats*, the *phatageri* (*manis tetradaactyla*), and the *elephant*. The two inferior maxillary bones are united into one very soon; also in the *many-hoofed* and *solid-footed quadrupeds*, and in the *mongoose* and *lamantin*.

The general figure of the lower corresponds usually with that of the upper jaw, already described. In the *saligrada* it is commonly a little shorter than the upper jaw, on account of the inferior incisor teeth being so long. In the *armadillo* and *four-toed manis*, the two sides of the jaw approach each other, and form a very acute angle at their symphysis.

The *ornithorhynchus* has the two pieces of the jaw joined to each other before their termination, and then bifurcate again. In the *echidna* the extremities are again joined; they are thin, flat, and round, or spoon-shaped.

The lower jaw of the *elephant* is rounded in the front, and resembles the human jaw more than could be supposed, from the general outline of the head in each.

The *ascending ramus* of the lower jaw forms nearly a right

angle with the body of that bone as in man, in the *lemur*, *cat*, *hedge-hog*, *squirrel*, *hare*, *beaver*, *kangaroo*, and most of the *saligrada*, *rhinoceros*, *elephant*, &c.; in fine, in most mammalia: but the mechanical operation of the jaw depends upon the situation of the condyle on which this bone moves, and the coronoid process by which it is chiefly moved, with respect to the body of the bone.

The *condyle* projects commonly back beyond the line of the angle formed by the body, and the ascending branch of the jaw. The more it is out of this line, or, in other words, the more the condyloid process approaches to the continuation of the body of the jaw, the more disadvantageous is the lever which this bone forms. The condyle, therefore, departs least from a right angle with the body of the bone in the *carnivorous quadrupeds*; a very little more in the *graminivorous*; and still more in the *monkey kind*. In the *ant-eater*, *manis*, *armadillo*, *ornithorhynchus*, and the *whale* tribe, the condyle does not form an angle, but is nearly in the same line with the body of the jaw, these animals not having any ascending branch to the lower jaw.

The nature of the lever, and the force of the moving power, depend chiefly upon the situation of the *coronoid process*, and the height and extent of this part.

This process is small in the *monkeys*. In the *lemurs* and the *digitigrada* it is large, and passes up into the temporal fossa, its point standing higher than the zygoma, and than the condyle, consequently the power of the temporal muscle is diminished, but the disadvantage of the position of the coronoid process is more than counterbalanced by the enormous size of the temporal muscles in the *digitigrade quadrupeds*.

In the *saligrada*, the coronoid process, in many instances, is short, and so far from the condyle, that it passes before the posterior grinding tooth, which is thereby placed between the moving power, and the point on which the jaw moves. The design of the force of the temporal muscle being carried so far forwards in the *saligrada*, is to increase the power of the gnawing teeth. The *hare*, *squirrel*, and *kangaroo*, however, have the coronoid process less advantageously situated, but they do not employ their teeth, like the *rats* and the *beaver*, as mechanical instruments.

In the *elephant*, the coronoid process advances upon the molar tooth, and passes on the outside of it as far as the one-third of the length of the tooth. It is a broad and very short process. In the *rhinoceros*, this process is at an equal distance from the condyle and last molar; and in the other animals of this order, it is generally nearer the back teeth than the condyle.

The *ruminating quadrupeds* have the coronoid process ascending into the temporal fossa, and its point passing nearly into a line with the condyle.

The *foliipeda* have it nearly the same: its point is not so far removed from the molar teeth.

In the *edentata* it is observed to approach very nearly to the condyle in the *armadillo*. It is directed outwards, in place of upwards, in the *echidna* and the *ant-eaters*. In the *four-toed manis* it is not to be perceived.

There is a short coronoid process in the genus *delfinus*, and the true *whales*, which is directed backwards, and only forms the superior angle of the long triangle which each side of the jaw presents in these animals. There is no trace of the coronoid process in the *cachalots* (*physeter*.)

The kind of motion of which the lower jaw is susceptible, is determined by the figure of the *condyles*, and the *cavities*, called *glenoid*, which receive them.

In the *carnivorous mammalia*, the condyle is longest in the transverse direction, and the glenoid cavity is adapted to it in shape and size: in many of these animals the articulation

of the lower jaw forms a perfect hinge, and only permits the separation of the lower from the upper jaw in the direction downwards. This is particularly to be observed in the *badger*, where the glenoid cavity has a projection before and behind, by which the condyle is partially inclosed in the joint: it even remains so after the parts are macerated, and the ligaments and cartilages are destroyed.

In the *monkeys*, the condyle is transverse, and a little oblique: the glenoid cavity is wide and shallow, and permits a degree of retraction, protrusion, and lateral motion of the lower jaw.

The freedom of motion in different directions is increased in the other quadrupeds, and is most so in the *ruminating* and *gnawing* tribes. In the latter, the figure of the condyle is exactly opposite to that of the *carnivorous* quadrupeds. It is a very thin oval tubercle, the length of which is from before backwards. The glenoid cavity is larger than the condyle, and so little concave, that the jaw has a very free lateral motion.

In the *elephant*, the condyle is short and round: the glenoid cavity, in place of being concave, is elevated in the middle. There is another condyle formed by the base of the zygomatic process: a joint, thus constructed, enables the animal to protrude and retract the jaw in a peculiar manner.

The glenoid cavity of the *hippopotamus* is situated behind the zygomatic process, in such a way as would seem to prevent any protrusion of the jaw.

In the *rhinoceros*, although the surface of the glenoid cavity is nearly flat, it is bounded posteriorly and internally by a long process, which must restrain its horizontal motion.

The articular cavity of the *tapir* has posteriorly an oblique process which opposes the lateral motion of the jaw.

The condyloid surface in the *ant-eater* is plane, and situated at the posterior extremities of the jaw. There is no glenoid cavity, but an articular surface corresponding to that of the jaw. In the other *edentata*, the condyle is a distinct eminence, smooth upon the surface, and applied to a similar surface of the zygomatic process, which supplies the place of the glenoid cavity.

The condyle of the *cetacea* is round, and very little eminent. The surface corresponding to the glenoid cavity is adapted to the figure of the condyle; they are united together, not merely by ligaments externally, but the articulating surfaces furnish many ligamentous bands, which consolidate the joint, and preclude every other motion of the jaw except that downwards.

The *os hyoides* of mammalia differs from that of the human subject with respect to the figure of the body of the bone, the relative magnitude of the cornua, and the existence of an additional osseous piece in place of the styloid ligament. This last is found in all the genera, with the exception of the *monkey* tribe: it is usually a long, slender bone, and is sometimes articulated in a particular depression situated at the place corresponding to the styloid process of the *os temporis*. In other cases it does not reach so far as the cranium, but is connected to it by ligament or cartilage. The cornua, which are called the large, in the human subject, are often consolidated with the body of the *os hyoides*, and those called the small cornua are sometimes very large. Cuvier has treated of all the varieties of the *os hyoides*, at great length, as he has of all the parts connected with the organs of deglutition or of voice. We shall notice some of the most remarkable deviations in the conformation of the *os hyoides*, from its structure in the human subject, and refer the reader to Cuvier's "Anatomic comparée" for details of the less important circumstances.

The *os hyoides* of the *ourang-outang* and *chimpanzee* resembles, almost exactly, the same bone in man. In the other *monkeys*, the body of the bone is broader, and either square or triangular. In the *common monkeys with long tails*, *not prehensile*, the *bare-lipped monkey*, and the *baboon*, it is convex in the front, and forms a sort of cavity upon the internal surface.

In the *howling baboons* this bone is very remarkable: it forms a bony sac under the root of the tongue. The parietes of the sac are thin and very elastic; they furnish a number of thin projections interiorly, by which the sac is divided into several irregular shaped apartments. This sac communicates posteriorly by a canal with the larynx. It is, therefore, subservient to the functions of that part, and enables the animals that possess it to produce that loud cry for which they are so distinguished.

The *os hyoides* of the *digitigrada* is composed, in general, of slender pieces: the body is cylindrical, and nearly straight. The anterior cornua are longer than the posterior: they are formed of two pieces; the second is sustained by the styloid bone. This last is usually larger than all the other parts of the *os hyoides*; the end next the temporal bone is broad, and covered with an articular surface.

The *os hyoides* of the *opossums* is flat, and nearly square: the cornua are joined to the angles: the large cornua are very broad at their base, and beat anteriorly, and end in a point: the small cornua are longer, cylindrical in their form, and enlarged at the posterior extremity.

In the *saligrada*, the figure of the *os hyoides* and its branches vary in their shape; in some genera they are broad; in others, narrow and slender. The *beaver* has a strong long oval process descending from the inferior edge of the body of the *os hyoides*. The anterior cornua are small and cartilaginous. Several of the other *saligrada* have also a process or projection from the body of the bone.

The *os hyoides* has a peculiar structure in the *echidna hystrix*. The body is formed of a flat, straight piece. The extremities of its anterior edge sustain the anterior cornua, which are cylindrical, directed forwards, and composed of but one piece. The styloid bone descends almost perpendicularly to meet these cornua. The posterior cornua are arched before: they are broad, flat, and articulated upon the sides of the body of the bone. The end of the posterior edge is convex, and is attached to a second piece, which descends parallel to the first as far as behind the body of the *os hyoides*, where it is joined to the one of the opposite side. Two other pieces are added to these, about the place of their junction, and separate from them upon the sides.

In many of the *multungulata* and *bifulca*, the posterior cornua are consolidated with the body of the bone. In the *elephant* this bone has the figure of a flattened lamina, a little arched upwards. The posterior branches are also flat, ascend obliquely backwards, and bend a little inwards. The styloid bone is bifid. Its posterior branch is arched, long, and ends in a point. The anterior is straight, shorter, and is articulated with the anterior cornua.

The *os hyoides* of the *cetacea* is both peculiarly situated and formed. The styloid bone is long; it proceeds very obliquely forwards and inwards, under the base of the tongue, where it is joined to the anterior corner of the same side. The anterior cornua are short; they pass directly backwards, to articulate with the middle of the convexity on the body of the bone: this last is flat and ankylosed with the posterior cornua, and represents the figure of a crescent, the points of which are turned backwards, and are not attached by ligaments to the thyroid cartilage.

MAMMALIA.

The number of vertebræ that compose the different regions of the spine of mammalia are subject to great variety, with the exception of those of the neck, which are the same number in man and all mammalia, besides the *three-toed sloth*, which has nine cervical vertebræ. When the neck is remarkably short, as in the *whale* tribe, the bodies of the cervical vertebræ are very thin, and a certain number of them consolidated by ankylosis into one bone, in which the distinctions of their original number and their processes can barely be seen.

The following table of the number of the vertebræ in the other parts of the spine, besides the cervical, is extracted from Cuvier's "Comparative Anatomy," and will render any further observations upon the numbers unnecessary.

TABLE of the Number of Vertebræ in mammiferous Animals.

Species.	Dorsal Verteb.	Lumbar Verteb.	Sacral Verteb.	Caudal Verteb.
<i>Man</i> - - -	12	5	5	4
<i>Ourang-outang</i> - - -	12	4	3	4

MAMMALIA.

The *cervical vertebræ* of the *monkey* tribe resemble those of the human subject, except that their spinous processes are stronger and not forked. They are very long in the species of *baboon* called *pongo*, in consequence of the large projecting face of this animal requiring an extensive attachment for the muscles, which raise and support the head.

In the *digitigrada* the spinous process of the second vertebra is very high, and extends upwards, or rather forwards, upon the atlas, and backwards upon the third vertebra. The transverse processes of the atlas are very large and flat on the front and back. These two vertebrae are altogether large. The pendent position of the head, in most of the *digitigrada*, makes the existence of strong muscles necessary for its support; the ligamentum nuchæ not being large in this family of quadrupeds. The short muscles at the back of the head contribute to the opening of the mouth of quadrupeds, and therefore should be strong in this carnivorous tribe.

The cervical vertebræ have no spinous processes in the *mole* and *sbrevis*. They appear, especially in the middle of the neck, as simple rings of bone, which admit of as free a motion upwards as in any other direction; their ligamentum nuchæ is ossified in parts.

In the *ant-eaters* and *armadillos* the bodies of the last six cervical vertebræ are large and compressed. They are consolidated to each other by ankylosis. All the *edentata* have a gutter in the anterior part of the bodies of the cervical vertebræ, in which the œsophagus is placed.

In the *camel*, *camelopard*, and other quadrupeds with long and flexible necks, the spinous processes are small, or almost obliterated. In the short-necked *ruminants*, as the *common cattle*, the transverse processes form two angles or double transverse processes. In both the *ruminants* and *solipeda* the bodies of the cervical vertebræ have a longitudinal ridge along their front.

The large quadrupeds, in consequence of the great weight of their heads, have that peculiar elastic substance which is called ligamentum nuchæ of a great strength. In the *horse*, the attachment of this part to the dorsal vertebræ is two hands broad. It is also connected by processes to some of the cervical vertebræ. In the *elephant* it is of an enormous size, and is inserted into a fossa at the back of the occipital bone.

In the *porpoise* and *dolphin*, the two first vertebræ are ossified together. In the *grampus*, the first three or four are ankylosed, and in the *cachalots* (*physeter*), the six last are united into one mass, and the bodies of the five middle vertebræ are reduced to an extreme thinness.

The *dorsal vertebræ* want spinous processes in some species of *bat*, and in others there are little tubercles in the place of the spinous processes. In all this genus the canal for lodging the spinal marrow is very wide where it passes through the dorsal vertebræ.

In all the long-necked and heavy-headed quadrupeds, the spines of the dorsal vertebræ are remarkably large and long, particularly in the *elephant*, *camel*, *camelopard*, and *horse*. The size of the spinous processes in these animals is necessary for the attachment of the ligamentum nuchæ.

The dorsal vertebræ of the *whale* tribe have at first the articular processes at the root of the transverse, but towards the ninth vertebra there are only the superior ones; for at this distance these articular processes turn backwards to the base of the spinous processes next the head, and form a kind of groove, which receives the preceding spinous process.

In the *lumbar vertebræ* there is great variety with respect to number, as is shewn by the foregoing table. When a quadruped is distinguished by a long body, it is usually found to

be occasioned by the number of the vertebræ of the loins. The spinous processes are long in the *dog* and *cat* genera, and have an inclination towards the head. This likewise takes place in some degree in the *monkey* kind.

The motion of the lumbar vertebræ is more or less restrained in most quadrupeds, by the external side of each posterior articular process having a point directed backward, so that the anterior articular process of the next vertebræ is received between two prominences.

The transverse processes are very large in the *ox*, *horse*, &c.; but are particularly so in the *whale* tribe, for the purpose of affording a surface for the attachment of the great muscles which move the tail, and give these animals the figure of fishes. There is a gradual change of form and size in the vertebræ of the posterior portion of the spine in the *cetacea*, but no marked distinction into the lumbar, sacral, and caudal vertebræ.

The breadth of the *sacrum* in man evidently arises from the erect position of his body. The few mammalia that occasionally stand upon the posterior extremities, as the *monkeys* and *bear*, have it broader than quadrupeds in general. In these last it is an elongated triangle, and is the continuation of the spine. This bone has large lateral processes at its anterior extremity in the *horse*.

The spinous processes are usually more eminent upon the sacrum in quadrupeds, than in man or the *monkey*. They nearly join to form a high sharp ridge in the *rhinoceros*, and many of the *bisulca*. This erect is very remarkable in the *mole*.

The *vampire bat* is the only example in mammalia of a total want of tail or caudal vertebræ. The sacrum of this animal terminates in a long point.

The *vertebræ of the tail* are usually very numerous in mammalia. Those next the sacrum have the same processes as the vertebræ of the other portions of the spine, and also a canal for holding the medulla spinalis. The vertebræ towards the extremity of the tail want the spinal canal, and have only small eminences or tubercles in place of the transverse or spinous processes. Those animals that employ their tail in swimming, as the *cetacea*; in building, as the *beaver*; or for progression by leaping, as the *kangaroo*, have the processes of the caudal vertebræ large and strong. The *beaver* has the breadth of the tail increased by the size of the transverse processes, and has also inferior spinous processes, which are larger than the superior, for the purpose of giving attachment to the great muscles by which this animal's tail is so forcibly depressed. The transverse processes only disappear very near the extremity of the tail in the *cetacea*.

In those quadrupeds that make much use of the tail, there is generally found a series of small double bones upon the under surface of the joints of the vertebræ, from the third or fourth to the seventh or eighth. In the *cetacea* they are very remarkable, and designed to perform the same offices as the inferior spinous processes of fishes' tails. They are sometimes ankylosed in pairs; but, generally, their edges touch, and each pair forms a sort of inverted Gothic arch somewhat similar to the inferior caudal spines of fishes.

Those that have prehensile tails, as one division of *monkeys*, have upon the inferior surface, and at the base of each body of the caudal vertebræ, two little tubercles, between which the flexor muscles of the tail pass.

The *ribs* of mammalia, both the true and the false, are very various with respect to number. They appear, however, to be not fewer in any instance than twelve, the number found in the human subject; as will appear by the following table, extracted from Cuvier's "Comparative Anatomy."

TABLE

MAMMALIA.

TABLE of the Number of Ribs in mammiferous Animals.

Species.	Total.	True.	False.
Man	12	7	5
Sai, or weeping monkey	13	9	4
Ourang	12	7	5
Pongo	12	7	5
Ternate bat	13	7	6
Common bat	12	7	5
Mole	13	8	5
Hedge-hog	15	7	8
Bear	14	9	5
Seal	15	10	5
Glutton	14	9	5
Raccoon	14	9	5
Otter	14	9	5
Lion	13	9	4
Cat	13	9	4
Wolf	13	9	4
Opoffum	13	7	6
Hare	12	7	5
Guinea pig	13	6	7
Three-toed sloth	16	8	8
Long-tailed manis	13	6	7
Elephant	20	7	13
Hog	14	7	7
Rhinoceros	19	7	12
Dromedary	12	7	5
Camelopard	14	8	6
Ox	13	8	5
Stag	13	8	5
Horse	18	8	10
Dolphin	13	6	7
Porpoise	13	6	7

The ribs are thick and broad in the large herbivorous quadrupeds, which are employed as beasts of labour; the strength of the spine, and its capability of sustaining great weights, depending very much upon the size of the ribs, and the figure they give to the trunk of the body.

In all the quadrupeds that protect themselves by rolling the head and extremities under the belly, when attacked by other animals, the ribs are remarkably strong, and closely set together. This conformation is to be observed in the common hedge-hog, but much more in some of the *edentata*, as the *armadillo* and the *ant-eaters*. The two first ribs of the *armadillo* are excessively large in proportion to the others, and in the *two-toed ant-eater* the ribs are so broad, that they overlap or rest upon each other, which gives this animal a greater security than it could derive from having the parietes of the thorax formed of one piece of bone.

The ribs of the *ornithorhynchus paradoxus* and *echidna bystrix* are curiously formed. The six true ribs are each composed of two pieces united by an intermediate cartilage, like the ribs of birds: the piece connected with the spine is longer than the other. The false ribs of these animals terminate in broad, flattened, oval plates, which are connected together by elastic ligaments.

The ribs have less curvature upon their sides in those quadrupeds that want clavicles than in the others. Those with clavicles have a chest shaped more nearly like the human, but in the quadrupeds which never use the anterior extremity as a prehensile member, the chest is flattened or narrowed upon the sides, especially towards the sternum. The *cetacea*, however, notwithstanding they have no clavicles,

have a cylindrical thorax, or one rather wider from side to side, than from above downwards.

The *sternum* in mammalia differs from the human generally in being longer in proportion to the body, being a rounder and narrower bone, and composed of a greater number of pieces.

The *ourang-outang* and the *pongo* have a flat broad sternum like man, but in all the other *monkeys* it is narrow, and composed of seven or eight bones.

In most quadrupeds it projects a little forwards beyond the line of the first rib, but in the *mole* this projection is very extraordinary; it passes forwards for almost as great a distance as the bone makes a part of the chest. This anterior portion is compressed upon the sides; is like a ploughshare, and sustains upon its sides the clavicles: by this structure the anterior extremities of the *mole* are carried forwards under the neck, occasioning the appearance of a want of neck, and the animal is enabled to excavate the earth for the admission of its body by the fore feet with extraordinary rapidity.

The anterior end of the sternum is curiously formed in the *bats*; it is enlarged into the figure of a T, the superior branches of which pass over the ribs and are joined to the clavicles.

The *hog* has the sternum narrow anteriorly, and large behind.

In the *cetacea*, the sternum is short, thin, and even broader in proportion to its other dimensions, than in man.

The *clavicle* is a bone required for the motions of the anterior extremity in the outward or inward direction. It exists necessarily, therefore, in all animals that employ the arm as a prehensile or mechanical member, or as a wing. There is a perfect clavicle in all the *monkey* tribe, the *chiroptera*, the *opossum* family: in the *mole*, *sbreus*, and *hedge-hogs*, amongst the *plantigrada*: in the *squirrels*, *rats*, *beaver*, *porcupine*, and *kangaroo*: in the *armadillos* and *ant-eaters*: in the *sloths*, &c.

The *digitigrada*, and some of the *saltigrada*, have an imperfect clavicle, (or *claviculare* of Vic d'Azir.) This is a short bone suspended merely by the muscles, and not attached either to the sternum or the scapula.

The clavicle is entirely wanting in the quadrupeds which employ their anterior extremities for progressive motion, as all the *hoofed* quadrupeds, the *daman*, the *cavy*, the *pangolins*, and in all the *cetaceous* tribe.

The clavicles of the *ourang-outang* resemble those of the human subject.

In the *bat*, they are remarkably long and strong.

The clavicle has an extraordinary thickness in the *mole*. It is nearly square, being more broad than it is long.

In the *two-toed ant-eater*, this bone has the figure of a rib.

In the *sloths*, the clavicle has a process from the extremity next the sternum, which forms nearly a right angle with the axis of the bone.

The *scapula* exists in all mammalia, but its posterior angle is most elongated in those species which have the most complicated motions of the anterior limbs or the arms.

It is in the *monkeys* and *lemurs* a triangular bone, of which the inferior or posterior edge, and that next the spine, are larger than the anterior side, but not so much larger as they are in man.

The *chiroptera* or *flying mammalia*, have the edge of the scapula next the spine very long, and the posterior very acute.

The body of the scapula in the *hedge-hog* is narrow, and the edge next the spine not extensive, but the whole is considerably elongated.

MAMMALIA.

In the *mole*, the scapula is a long narrow bone, which does not exhibit the distinction of supra-spinous and infra-spinous surfaces upon the back; there being no spine except near the posterior margin, and before the tubercle which corresponds to the acromion. The scapula of the *mole* lies parallel to the vertebræ, and resembles a good deal both in form and position the same bone in *birds*.

In quadrupeds, generally, the edge of the scapula next the spine is rounded, and the posterior angle thus rendered blunt. The spinous process of the bone is situated about the middle of the body, or even lower.

In those quadrupeds that want clavicles, the acromion scapulae is not so prominent as when these bones exist, and there is another process which points backwards almost perpendicular to the spine. This process is also found in the *hedge-hog* and *opossums* which have clavicles. In the *hare* the recurrent process is very long.

The coracoid process of the scapula is commonly wanting in those that have only the rudiments of clavicles, and more constantly where these bones do not exist.

In the *ruminants* and *solid-footed* quadrupeds, the scapula has neither acromion, coracoid, nor recurrent process.

The *cetacea* have a thin flat scapula. The edge next the vertebræ is round and broad, so that the whole bone has much the figure of a saw. In the genus *delphinus* the spinous process is near the cervical edge of the bone, and does not form an angle with the infra-spinous surface, of which it seems the continuation. The supra-spinous fossa has a deep concavity, which appears to arise from a deficiency in ossification. Above the humeral angle, there is a projecting plate continuous with the spinous process, which appears to correspond with the acromion. In the other genera of the *whale* tribe, the supra-spinous fossa is stated by Cuvier as being less distinct.

The *humerus* of mammalia varies in length and thickness, and in the elevation of its processes.

This bone is longer in the *bat* and the *tardigrade* quadrupeds, in proportion to the rest of the anterior extremity, than the humerus of the human subject. In quadrupeds, generally, however, it is much shorter. Those that have the metacarpal bones long, have the humerus so short, that it is concealed in a great measure by the muscles of the limb and the skin of the thorax, from whence the ancient anatomists fell into the error of supposing, that the elbow was turned forwards in quadrupeds, the joint of the carpus being mistaken for that of the elbow. It is customary with people ignorant of comparative anatomy, still to miscall the part corresponding to the wrist in quadrupeds the elbow.

This bone is also very short in the *cetacea*, and has a large spherical head.

The shortest humerus, and the thickest with respect to its length, is found in the *mole*, which animal is distinguished by many peculiarities in its skeleton. It has besides a very singular form. The two ends of the bone are so much expanded and changed from the usual appearance of these parts, that they are with difficulty recognized. There is a small process which takes the place of the head of the bone, and is articulated with the scapula. There is another articular surface, apparently corresponding to the great tuberosity, which also forms a joint with the clavicle: between these two the top of the humerus is deeply hollowed. The crest of the little tuberosity is so large, that it resembles a square placed vertically, with the linea aspera at top. The body of the bone is bent towards the top, so that the part which forms the joint with the ulna points directly upwards; by which means the elbow of this animal stands above the shoulder, and the palm of the hand is turned outwards. This forma-

tion of the arm enables the *mole* to throw the earth to each side when it buries itself.

The humerus of the *beaver* is considerably enlarged at the condyles. It has also a large transverse process, at about the distance of one-third from the top.

In the *hog*, *tapir*, and *rhinoceros*, the humerus has the great tuberosity divided into two parts. The linea aspera also of the *rhinoceros* terminates in a very high tubercle. Something similar exists in the *horse*.

The *bisulca* generally have the great tuberosity very high, and the linea aspera prominent.

In most quadrupeds, the great tuberosity is elevated above the head of the humerus.

In those mammalia that employ the upper extremity for other purposes than walking, the bones of the fore-arm exist distinctly, and preserve nearly their proper proportions, as in man. But in the true quadrupeds, the *ulna* declines in size, and becomes in some a mere appendage to the *radius*, which is the principal bone of the fore-arm in most quadrupeds. The existence of two bones in the fore-arm is only necessary on account of the motion of supination. Where the supine state of the member would be inconvenient in the progression of the animal, we find the *ulna* either ankylosed to the *radius*, or entirely absent.

The *ulna* in the *ourang-outang* resembles that of man. In the *monkey* tribe, generally, the coronoid process of the *ulna* is narrower, and the bone is more compressed than in man. The articular surface of the *radius* also is deeper. There is often a hole found in the cavity at the back of the humerus, which receives the olecranon.

In the *digitigrada*, the olecranon is compressed, and projects more backwards; and the coronoid process is diminished before. In the *dog* there is a little cavity in the end of the *radius*, for the reception of the external process, or lesser head of the humerus, and a ridge for the furrow that divides it from the anterior part of the pulley, by which the rotation of the *radius* is a good deal restrained.

In some of the *saligrada*, as the *cavy*, the *hare*, the *rat*, and others, the coronoid process of the *ulna* is entirely obliterated, and the *radius* covers the front of the articulation. The head of the latter bone forms a hinge-like joint, having a cavity for the lesser head of the outside of the humerus, and a ridge for the anterior part of the pulley, that is occupied in man by the coronoid process of the *ulna*.

In the *rhinoceros*, the *tapir*, and *hog*, the *ulna* is entirely behind the *radius*. They move as one bone upon the pulley of the humerus. The lesser head of the latter bone is quite effaced inferiorly. The *ulna* and *radius* of these animals are notwithstanding distinct, but still are incapable of rotation.

In the *elephant*, the coronoid process is divided into two ridges with hollow surfaces, which revolve upon the projecting parts of a single hinge. Between these the head of the *radius* is placed. It is small, and sustained by the external ridge, and the middle channel of the hinge or pulley: for as it is oblong, it cannot turn upon it. The lower part of the *radius* is directed towards the inner side of the leg, which is therefore always in the pronated position. The inferior head of the *ulna* is larger than that of the *radius*, which Cuvier says does not occur in any other animal in this whole class.

In the *clown* and *solid-footed* quadrupeds, the *ulna* is united immovably to the *radius* almost throughout its whole length. This union is osseous after a certain period, so that they might be considered as one bone. They form together a hinge-like joint, with the pulley on the end of the humerus, which does not admit of any rotatory movement.

Where the ankylosis is incomplete of the two bones in
these

MAMMALIA.

these animals, there is a short fissure to be seen between them. This exists above and below in the *camelopard*, *stag*, and *gazelle*: only at the upper part of the bones in the *horse*, *sheep*, and *ox*, and is not perceived in the *camel* and *dromedary*; but in all these animals the original distinction between these bones is marked by a furrow or groove.

All the hoofed quadrupeds have the anterior extremities permanently in the state of pronation; that is, with what is called the back of the wrist turned forwards.

In the *bat* and *galeopithecus*, there is only one bone in the fore-arm, or at least a mere styiform rudiment of the other. This single bone Blumenbach has called the ulna, and Cuvier the radius. The latter is certainly the proper appellation. The motions of the anterior extremity, as a wing, require the part corresponding to the fore-arm to be constantly in a state of pronation.

In the *mole*, the olecranon is very long, and terminates in a transverse plate: the whole ulna is very thin. The edge of the head of the radius is prolonged under the little head of the humerus, and seems to be incapable of rotation. The position of the fore-arm and hand of the *mole* is singular. The elbow, as before observed, is turned upwards; the palm of the hand outwards, and the thumb downwards. This is pronation carried to an extreme, which is the most suitable position of the hand for its peculiar office in this animal of scooping out the earth.

The *seal*, instead of the concavity for surrounding the pulley of the humerus, has upon the ulna one surface, which forms a joint with the humerus, and another oblique one for the radius. This last has a large head, the inner edge of which runs in a pulley. The body of the radius is very broad downwards.

In the *lamantin*, the radius and ulna are anchylosed together at both ends.

In the *cetacea*, the bones of the fore-arm are placed close to each other, but not united by ossific substance: they are flattened, and connected so intimately with the humerus and the carpus by ligaments and cartilage, that they have none of the motions of a regular articulation. They merely admit of a degree of flexion, forwards and backwards, sufficient to communicate the necessary pliancy to the fin.

The number and the figure of the bones composing the *carpus* differ from what we find in the human subject, and amongst the different tribes of mammalia themselves.
